(Received 15 November 2011; revised manuscript received 16 March 2012; published 26 March 2012)

We report analytical and numerical results on the two-particle states of the polaronic \( t-\text{J}_p \) model derived recently with realistic Coulomb and electron-phonon (Fröhlich) interactions in doped polar insulators. Eigenstates and eigenvalues are calculated for two different geometries. Our results show that the ground state is a bipolaronic singlet, made up of two polarons. The bipolaron size increases with increasing ratio of the polaron hopping integral \( J \) to the exchange interaction \( \text{J}_p \), but remains small in the whole range \( 0 \leq t/J_p \leq 1 \). Furthermore, the model exhibits a phase transition to a superconducting state with a critical temperature well in excess of 100 K since the small bipolarons are perfectly mobile. In the range \( t/J_p \ll 1 \), there are distinct charge and spin gaps opening in the density of states, specific heat, and magnetic susceptibility well above \( T_c \).

With few exceptions,\(^1\) it is widely believed that the conventional Bardeen-Cooper-Schrieffer (BCS) theory and its intermediate-coupling Eliashberg extension\(^2\) do not suffice to explain high-temperature superconductivity. On the contrary, there is growing understanding that the true origin of high-temperature superconductivity should be found in a proper combination of the Coulomb repulsion with a significant electron-phonon interaction (EPI).\(^3\) The many-body theory of strongly correlated electrons and phonons was originally developed with the on-site Hubbard repulsion and the short-range Holstein EPI using analytical strong-coupling expansion\(^4\) and powerful numerical techniques\(^5\) in the framework of the Hubbard-Holstein and Holstein–\( t-\text{J} \) models.\(^6\) Also the many-body Coulomb-Fröhlich model, which takes into account a finite range of realistic interactions, was proposed\(^7\) and studied analytically\(^8\) and numerically,\(^9\) showing a rich phase diagram with a polaronic Fermi-liquid, superconductivity induced by mobile bipolarons and a charge-segregated phase. In these and many other studies\(^10\) both interactions were introduced as input parameters not directly related to the material.

Recently it has been shown that, in highly polarizable ionic lattices, the bare long-range Coulomb and electron-phonon interactions almost negate each other, giving rise to a physics described by the polaronic \( t-\text{J}_p \) model\(^11\) with a short-range polaronic spin-exchange \( \text{J}_p \) of polaronic origin,

\[
\mathcal{H} = - \sum_{i,j} \tau_{\sigma \sigma'} c_i^\dagger c_j + 2 \sum_{m \neq n} \text{J}_p (\mathbf{m} - \mathbf{n}) \times \left( S_m \cdot S_n + \frac{1}{4} n_m n_n \right).
\]

where \( S_m \) is the spin over \( \mathbf{n} \neq \mathbf{m} \) counts each pair once only, \( S_m = (1/2) \sum_{\sigma, \sigma'} c_{m \sigma}^\dagger \tau_{\sigma \sigma'} c_{m \sigma'} \) is the spin \( 1/2 \) operator (\( \tau \) are the Pauli matrices), \( n_m = \sum_{\sigma} c_{m \sigma}^\dagger c_{m \sigma} \) is the on-site occupancy since the on-site Coulomb repulsion \( U \) on the on-site occupancy since the on-site Coulomb repulsion is negated by the Fröhlich EPI. The hopping integral \( t_{ij} \) leads to the coherent (bi)polaron band while the antiferromagnetic exchange \( \text{J}_p \) bounds polarons into superlight intersite bipolarons. Moreover, the sign “+” instead of “−” in the last density-density interaction term in (1) provides an effective repulsion between pairs, preventing their clustering,\(^13\) while the repulsive \( t-\text{J} \) model favors a phase separation.

Also different from any model proposed so far is that all quantities in the polaronic \( t-\text{J} \) Hamiltonian (1) are defined through the material parameters, in particular \( t_{ij} = T(m - n) \exp[-g^2(m - n)] \) with

\[
g^2(m) = \frac{2\pi e^2}{k h \omega_0 V} \sum_q \frac{1 - \cos(q \cdot m)}{q^2}
\]

and

\[
\text{J}_p(m) = T^2(m)/2g^2(m)\hbar \omega_0,
\]

where \( \kappa = \epsilon_\infty \epsilon_0/(\epsilon_0 - \epsilon_\infty) \) and \( V \) is the normalization volume. Here the high-frequency \( \epsilon_\infty \) and the static \( \epsilon_0 \) dielectric constants as well as the optical phonon frequency \( \omega_0 \) and the bare hopping integrals in a rigid lattice \( T(m) \) are measured and/or found using first-principle density functional theory\(^14\) in a parent polar insulator. Our \( \text{J}_p \) describes the spin exchange of carriers doped into polar insulators as, for instance, oxygen holes in the cuprates, rather than antiferromagnetic correlations of copper spins in the parent insulator, which are well described by the conventional \( J \). The polaronic \( \text{J}_p \) (on the order of a few hundred meV or more) is larger than \( J \approx 100 \) meV.

in the response functions of the model.

These results allow for some insight into a possible superconducting phase transition and pseudogap signatures in the response functions of the model.

According to the Mermin-Wagner theorem, there should be no phase transition at finite temperatures in one and two dimensional systems. However, ED results, additional information on the two-particle dynamics can be obtained by considering the following two-particle singlet basis for an infinite lattice:

\[
|m,k\rangle = \begin{cases} 
0 & \text{if } m > 0 \\
\sqrt{2}e_1(k) & \text{if } m = 0 \\
\sqrt{2}e_2(k) & \text{if } m = 0 \\
\sqrt{2}e_3(k) & \text{if } m = 0 \\
0 & \text{if } m = 0 \\
e_1(k) & \text{if } m = 0 \\
0 & \text{if } m = 0 \\
\vdots & \text{if } m = 0 \\
\vdots & \text{if } m = 0
\end{cases}
\]

For the analyzed one-dimensional geometries the matrix representation of the \(t-J_p\) Hamiltonian in this basis is

\[
\hat{H}(k) = \begin{pmatrix}
0 & \sqrt{2}e_1(k) & \sqrt{2}e_2(k) & 0 & \ldots \\
\sqrt{2}e_1(k) & -J_p + e_2(k) & e_1(k) & e_2(k) & \ldots \\
\sqrt{2}e_2(k) & e_1(k) & e_3 & e_1(k) & \ldots \\
0 & e_2(k) & e_1(k) & 0 & \ldots \\
\vdots & \vdots & \vdots & \vdots & \ddots
\end{pmatrix}
\]

where \(e_1(k) = -2t \cos(ka/2)\) and \(e_2(k) = e_3 = 0\) for the chain while we have \(e_1(k) = -2t \cos(ka/4)\), \(e_2(k) = -2t \cos(ka/2)\), and \(e_3 = -J_p\) for the zigzag ladder.

The eigenvalues of the tridiagonal matrix \(\hat{H}(k)\) determine the energy dispersion \(E(k)\). In the limit \(t \to 0\), \(e_1(k) \to 0\), so that the ground-state energy is \(-J_p\), in agreement with the ED results showed so far. For any \(t > 0\), the problem is still solvable by requiring the system wave function to decay exponentially in the region where the potential vanishes. In the case of a chain, the energy dispersion can be derived from a cubic equation that, in the \(t \ll J_p\) limit, gives

\[
E_s(k) = -J_p - (12t^2/J_p) \cos^2(ka/2) + O(t^4)
\]

with a quadratic contribution with respect to the hopping term. On the contrary, in the same limit the corresponding dispersion for the zigzag ladder has been found to be linear in \(t\):

\[
E_s(k) = -J_p - t[\cos(ka/2) + \sqrt{1 + 4 \cos^2(ka/4)}] + O(t^2).
\]

As shown in Fig. 2, the energy dispersions at \(k = 0\) obtained for the chain and the zigzag ladder are in perfect agreement with ED and variational results on finite clusters in the whole range of \(0 \leq t/J_p < 1\).

These results allow for some insight into a possible superconducting phase transition and pseudogap signatures in the response functions of the model.

According to the Mermin-Wagner theorem, there should be no phase transition at finite temperatures in one and two dimensional systems.
dimensions (1D and 2D) since there is no continuous symmetry breaking. However, a finite temperature phase transition in 2D can exist via the Berezinskii-Kosterlitz-Thouless (BKT) mechanism.\textsuperscript{18,19} For a hard-core 2D Bose gas, where the Bose-Einstein condensation does not occur,\textsuperscript{20,21} a phase transition to a superfluid state is expected.\textsuperscript{19} In particular, it has been shown\textsuperscript{22} in the dilute limit \( \ln(1/n_b r^2) > 1 \) that the critical temperature is

\[
T_c = 2\pi \hbar^2 n_b / k_B m^* \ln(1/n_b r^2),
\]

where \( n_b \) is the boson density per unit area and \( r \) is the range of the boson-boson repulsion. In our case \( r \approx a \) and \( m^* \) is the bipolaron mass.

To estimate the bipolaron effective mass for a 1D chain, one can use our dispersion (7), which gives \( m^{**} = \hbar^2 J_p / 6a^2 r^2 \). In the case of a zigzag ladder, taking into account only the linear contribution in \( t/J_p \) results in an overestimated \( m^{**} \) with \( m^{**}/m^* \approx 5 \) where \( m^* = \hbar^2 / 2ma^2 \) is the polaron mass.\textsuperscript{16} Numerical results obtained by solving the eigenvalue problem of (6) show in fact that the ratio \( m^{**}/m^* \) is below this estimate (Fig. 3). In particular, for \( t \approx J_p \) we have \( m^{**} \approx 2m^* \) for both chain and zigzag ladder geometries.

Since the effective mass is proportional to \( 1/t^2 \) or \( 1/t \), one may conclude that \( T_c \) should increase as \( t \) or \( t^2 \) with the polaron hopping integral. On the other hand, our ED results, Fig. 1, show that the probability \( P_{0b}(t/J_p) \) to find a hard-core tightly bound singlet decreases as the hopping increases. At sufficiently low density, BEC should not depend on whether the bipolarons are nearest neighbor or next nearest neighbor, so long as they are bound and the bipolaron spacing is much greater than the typical polaron separation. On the other hand when bipolarons overlap, their condensation appears in the form of the Cooper pairs in the momentum space with a lower critical temperature, rather than in real space (BEC-BCS crossover).\textsuperscript{2} Hence, bounds for the critical temperature can be estimated by weighting Eq. (9) with \( P = P_{0b}(t/J_p) \) as \( T_c' \approx P_{0b}(t/J_p)T_c \). As shown in Fig. 3, despite the low carrier density, the critical temperature is about 200 K with the chain and the zigzag ladder effective mass. In particular, \( T_c' \) obtained for the chain should not be considered as strictly related to the geometry but to the values of \( m^{**} \) that could be a crude (but quite reliable) estimation of the bipolaron effective mass for a 2D lattice in the low-density limit. In the case of cuprate superconductors with the polaron binding energy in the range 0.5 eV < \( E_p \) < 1.0 eV and 0.3 eV < \( J_p \) < 1.0 eV (Ref. 11) one gets the realistic value of the bare hopping integral 0.2 eV < \( T(a) \) < 0.4 eV that gives 0.05 < \( t/J_p \) < 0.27 and the critical temperature 20 K < \( T_c' \) < 100 K at \( n_b = 0.01 \).

Let us finally analyze the (pseudo)gap features in the density of states (DOS) and the spin susceptibility \( \chi_s \) of the polaronic \( t-J_p \) model at high temperatures well above \( T_c' \), when all carriers are nondegenerate. It is convenient to introduce the “occupation density of states” (ODOS), \( \rho(\omega, T) \), by weighting the standard temperature-independent DOS with the Fermi-Dirac and the Bose-Einstein distribution functions,

\[
\rho(\omega, T) = f_s(\omega, T)N_s(\omega) + 2f_p(\omega, T)N_p(\omega),
\]

where

\[
N_{s,p}(\omega) = \frac{a}{2\pi} \int_{-\pi/a}^{\pi/a} d\delta[\omega - E_{s,p}(k)],
\]

and \( f_s(\omega, T) = [\exp((\omega - \mu_{s,p})/k_B T) + 1]^{-1} \). Here \( E_{s,p}(k) \) is the (bi)polaron dispersion and \( \mu_s = 2\mu, \mu_p = \mu \) are the chemical potentials of bipolarons and single polarons, respectively, with \( \mu < E_s(0)/2 \).

In the \( t = 0 \) limit, according to (4) we have three different two-particle energy levels with \( E_s(k) \) and \( E_p(k) \) separated by \( J_p \). However, at low carrier density and temperature, the highest energy level does not contribute to ODOS and we observe two sharp peaks at \( \omega/J_p = -1 \) and \( \omega/J_p = 0.0 \) with a suppression of ODOS around \( \omega/J_p = -0.5 \). Hence there is a single charge/spin pseudogap, \( \Delta_c = \Delta_s = J_p \). The ODOS for finite values of \( t/J_p \) and temperatures is shown in Fig. 4 with some Gaussian broadening in the \( \delta \) function in Eq. (11), modeling for instance disorder effects. At any \( t \neq 0 \), the two peaks become wider as \( t/J_p \) increases and the gap between the bipolaron and the unpaired polaron bands gradually closes. With increasing temperature the single-particle polaron band is more populated along with the increasing population of higher energy levels in the bipolaron band, so that ODOS reflects a competition between bound and unbound states in the response functions. In particular, the behavior of the spin susceptibility indicates the presence of a finite spin-gap \( \Delta_s \) that decreases gradually as \( t \) becomes comparable with the binding energy.
$J_p$.\(^{13}\) coherently with the suppression of the probability to find a bipolaron in the nearest-neighbor configuration (Fig. 1). With increasing temperature, the number of occupied states within the pseudogap also increases. Without many-body correlation effects (i.e., a screening of the Coulomb and electron-phonon interactions at finite carrier densities\(^{2-5}\)), the pseudogap itself does not depend on temperature; it is a matter of whether the temperature is high enough for single-polaron states to have significant occupation. Hence a characteristic pseudogap temperature \(T^*\) exists in our model above which the pseudogap is suppressed, but it is a crossover temperature rather than a critical temperature. Further signatures of pseudogap opening are also found in the specific heat\(^{13}\) where the Schottky anomaly is induced by thermal excitation within the bipolaronic and the polaronic bands.

In conclusion, we have described some key features of the $t$-$J_p$ Hamiltonian in the low-density limit. We have shown that the ground-state configuration is a small bipolaron singlet. Depending on the competition between the hopping $t$ and the polaronic exchange interaction $J_p$, the bipolaron size changes but remains small in the whole range $0 \leq t/J_p \leq 1$. We have also argued that, in the 2D case, the presence of small light bipolarons results in a phase transition to a superconducting state at a critical temperature in excess of a hundred degrees Kelvin. Finally, the spin susceptibility and the specific heat of the model revealed charge and spin gaps. Because of the presence of a continuum spectrum, there is no true ground-state gap at any finite value of the polaron hopping $t$. However, strong evidence of a finite pseudogap has been found in the range where $t < J_p$ above \(T_c\).
