(Received 7 November 2012; published 15 January 2013)

We show theoretically that the dynamics of cold atoms in the lowest-energy band of a stationary optical lattice can be transformed and controlled by a second, weaker, periodic potential moving at a constant speed along the axis of the stationary lattice. The atom trajectories exhibit complex behavior, which depends sensitively on the amplitude and speed of the propagating lattice. When the speed and amplitude of the moving potential are low, the atoms are dragged through the static lattice and perform drifting orbits with frequencies an order of magnitude higher than that corresponding to the moving potential. Increasing either the speed or amplitude of the moving lattice induces Bloch-like oscillations within the energy band of the static lattice, which exhibit complex resonances at critical values of the system parameters. In some cases, a very small change in these parameters can reverse the atom’s direction of motion. In order to understand these dynamics we present an analytical model, which describes the key features of the atom transport and also accurately predicts the positions of the resonant features in the atom’s phase space. The abrupt controllable transitions between dynamical regimes, as well as the associated set of resonances, provide a mechanism for transporting atoms between precise locations in a lattice, as required for using cold atoms to simulate condensed matter or as a stepping stone to quantum information processing. The system also provides a direct quantum simulator of acoustic waves propagating through semiconductor nanostructures in sound analogs of the optical laser (saser).

I. INTRODUCTION

Cold atoms in optical lattices created by two or more counterpropagating laser beams provide a clean, flexible, physical environment for studying quantum particles in periodic potentials. Key advantages of such systems include the tunability of the lattice, low dissipation, and the ability to directly control and measure the atoms’ internal state. When the atoms are cold enough for the de Broglie wavelength, corresponding to the atoms’ center-of-mass motion, to span several wells of the lattice potential, the associated energy eigenvalues form bands of allowed energies separated by band gaps. The dynamics of atoms in energy bands is of particular interest due to the similarities to the behavior of electrons in solids [1–6]. For example, atoms confined to a single energy band and subject to a constant force have been shown to Bragg reflect and perform many Bloch oscillations [7–12]: a phenomenon well known, but harder to realize, in solid state physics [13,14].

Recently, there has been increased experimental interest in nonlinear phenomena relating to the transport of atoms in optical lattices. In particular, it has been shown that moving optical lattices can transport cold atoms along distances as far as 20 cm [15]. In addition, unusual band-structure properties have been revealed by experiments with a moving optical lattice [16], critical velocities in such systems have been identified [17], the stability of superfluid currents in systems of ultracold bosons have been studied [18], and the phenomenon of stochastic resonances has been predicted to play an important role in transport through dissipative optical lattices [19]. For single-atom transport, both lensing [20] and the dynamics and control [21–26] of Bose-Einstein condensates have been observed and studied.

In this paper we propose a method to control precisely the dynamics of atoms moving through a stationary optical lattice by introducing an additional moving periodic optical potential. We demonstrate that the combined effect of the two lattices induces multiple sharp resonances, which can be exploited to tailor the atomic motion. Also, this system has a direct counterpart in semiconductor physics. Specifically, it models the electron dynamics induced by an acoustic wave propagating through semiconductor nanostructures [27], a topic of growing interest due to the recent development of coherent sources of phonons (sasers) [28–30], which are analogs of the optical laser.

The paper has the following structure. In Sec. II we introduce the semiclassical equations of motion for an atom in a stationary optical lattice driven by a propagating optical potential. Analysis of the equations reveals the distinct dynamical regimes of this system and the abrupt transitions between them. In Sec. III we study how the speed of the propagating potential affects the average velocity of atoms in the stationary lattice. Section IV explores how the atom’s initial position affects transitions between the various dynamical regimes. In Sec. V we compare our semiclassical results with full quantum calculations. Finally, in Sec. VI we draw conclusions and propose experiments to study the transport phenomena that we have identified.

II. SEMICLASSICAL ATOM TRAJECTORIES

We consider a cloud of cold, noninteracting, sodium atoms [11,31–34] initially in the lowest-energy band of a one-dimensional stationary optical lattice (SOL), taking the potential-energy profile of each atom to be $V_{\text{OL}}(x) = V_0 \sin^2(\pi x / d)$ [Fig. 1(a)]. The lattice period $d = 294.5$ nm and its depth is $V_0 = 563$ peV $= 5.5E_R$, where $E_R = 103$ peV is the recoil energy. The energy versus crystal momentum dispersion relation for the lowest-energy band is, to
a good approximation, \( E(p_x) = E_0 + \Delta[1 - \cos(p_x d/\hbar)]/2 \) [Fig. 1(b)], where \( E_0 \approx 200 \) peV and \( \Delta = 24.4 \) peV is the bandwidth. To this system we apply an additional moving optical potential (MOP), which propagates along the \( x \) axis at velocity \( v_M \), creating a position and time- (t-) dependent potential-energy field \( V_M(x,t) = U_M[1 - \sin(k_M x - \omega_M t)]/2 \) [Fig. 1(c)], where the wave number \( k_M = 2\pi/\lambda_M \), \( \lambda_M \) is the wavelength, and \( \omega_M = k_M v_M \) is the angular frequency. Such a field can be generated by counterpropagating laser beams whose frequencies are slightly detuned by \( \delta\omega \). The velocity of the MOP is then \( v_M = \delta\omega/2k_M \) [15,16,19].

The semiclassical Hamiltonian for an atom in the lowest-energy band of the stationary optical lattice, and subject to the moving potential, is \( H(x,p_x,t) = E(p_x) + V_M(x,t) \). The corresponding Hamilton equations of motion are

\[
\frac{\partial p_x}{\partial t} = \frac{U_M}{2} k_M \cos[k_M(x + x_0) - \omega_M t],
\]

\[
\frac{\partial x}{\partial t} = \frac{\Delta d}{2\hbar} \sin\left(\frac{p_x d}{\hbar}\right).
\]

We solve Eqs. (1) and (2) numerically to calculate the trajectories starting from rest with \( x_0 = x(t = 0) = 0 \) and \( v_x(t = 0) = 0 \). To characterize the transport of an atom through the SOL, we calculate the time-averaged velocity \( \langle v_x \rangle \), over a period of 0.25 s.

The solid curve in Fig. 2 shows \( \langle v_x \rangle \), calculated as a function of \( U_M \) for \( \lambda_M = 20d \) and \( v_M = 2.5 \) mm s\(^{-1}\). The curve reveals that for very low \( U_M \), \( \langle v_x \rangle \) increases exponentially from 0 with increasing \( U_M \), until \( U_M \) reaches a critical value \( U_M^c \approx 2.5 \) peV = \( 2.43 \times 10^{-2}E_R \) (red vertical dashed line), at which point \( \langle v_x \rangle = v_M \) (marked by the upper horizontal dotted line). As \( U_M \) increases beyond \( U_M^c \), \( \langle v_x \rangle \) remains pinned at \( v_M \) until \( U_M \) reaches a second critical value \( U_M^c \approx 16 \) peV = \( 0.156E_R \) (blue vertical dot-dashed line) where the average velocity begins to decrease abruptly with increasing \( U_M \). Thereafter, increasing \( U_M \) gives rise to a series of resonant peaks (arrowed in Fig. 2).

To understand the form of the \( \langle v_x \rangle \) versus \( U_M \) curve, in Fig. 3 we show atom trajectories for three values of \( U_M \) corresponding to three distinct dynamical regimes. Figure 3(a) shows \( x \) versus \( t \) for a trajectory within the low-field regime when \( U_M = 1 \) peV = \( 9.74 \times 10^{-3}E_R \) (\( < U_M^c \)), which is marked by a red dashed line in Fig. 2). In this case, the atom orbit comprises a uniform drift, with mean velocity \( \approx 75 \mu\text{m s}^{-1} \), and superimposed periodic oscillations. The electron velocity \( v_\perp > 0 \) when \( V_M(x,t) < U_M/2 \) [white regions in Fig. 3(a)] and \( v_\perp < 0 \) when \( V_M(x,t) > U_M/2 \) [gray regions in Fig. 3(a)].
The first local maximum of $E'(p_x)$, which occurs when $p_x \approx \hbar k_M x_0$, is an almost harmonic function of $t$. Since $E'(p_x)$ is the kinetic energy in the moving frame $E'(p_x) = H'(x', p_x)$, we can approximate the trajectory in Fig. 3(c) by the expression

$$ x(t) \approx v_M t + \lambda_M [1 - \cos(\omega_R t)]/4, \quad \omega_R = \text{frequency for motion to and fro across the potential well} [27]. $$

In this wave dragging (WD) regime, the atom is trapped in a single well of the MOP, but as the well moves, it drags the atom through the SOL. Figure 3(d) shows that the atom is able to oscillate in a parabolic region of $E'(p_x)$ between the two $p_x$ values (solid circles) where $E'(p_x) = U_M'/2$. Since the atom remains in the almost parabolic region of $E'(p_x)$, $x(t)$ is an almost harmonic function of $t$. Therefore we can approximate the trajectory in Fig. 3(c) by the expression $x(t) \approx v_M t + \lambda_M [1 - \cos(\omega_R t)]/4$, where $\omega_R$ is the frequency for motion to and fro across the potential well [27].

Increasing $U_M$ in the WD regime initially has no qualitative effect on the trajectories, which continue to be dragged and are of the form $x(t) = v_M t + f(t)$. However, as $U_M$ increases, the atom can access increasingly nonparabolic parts of $E'(p_x)$ and thus $f(t)$ becomes less harmonic. Eventually, though, $U_M$ becomes large enough for the atom to traverse the first local maximum of $E'(p_x)$ [arrowed in Fig. 3(d)]. Thereafter, the atom can reach the edge of the first Brillouin zone and its trajectory in $p_x$ changes abruptly from closed to open. In this regime, the atom can traverse several minizones, allowing it to Bragg reflect and perform Bloch oscillations. The first local maximum of $E'(p_x)$ occurs when $p_x = \hbar k_M x_0 - \Delta$, which is a positive constant.

For the parameters considered, Eq. (6) gives $U_M'' \approx 2.5 \text{ peV} = 2.43 \times 10^{-2} E_R$, which compares well with the transition to the region where $E'(p_x) = U_M'/2$ (upper horizontal dotted line in Fig. 2).
maximum in $E'(p_x)$ [27]:

$$
U_M^h \approx \frac{2}{1 - \sin k_M x_0} \left[ \Delta - \frac{\hbar \pi v_M}{d} + \frac{2\hbar^2 v_M^2}{\Delta d^2} \right].
$$

The vertical blue dot-dashed line in Fig. 2 shows the value of $U_M^h$ obtained from Eq. (7) for $x_0 = 0$, which coincides exactly with the abrupt suppression of $\langle v_x \rangle$.

Figure 3(e) shows the atom’s trajectory when $U_M = 150$ peV = $1.46 E_R > U_M^h$. In this regime, the atom undergoes fast oscillations [bracketed in Fig. 3(e)], interrupted by jumps in the orbit (arrowed). Initially, for $t = 0$ and $x(t) = p_x(t) = 0$, the driving force on the atom is maximal and therefore $p_x$ increases rapidly. As a result, the atom traverses several local maxima and minima in $E'(p_x)$ [between circles in Fig. 3(f)]. Subsequently, $p_x$ starts to decrease, triggering another burst of Bloch oscillations, until $p_x$ reaches its minimum possible value [left-hand solid circle in Fig. 3(f)]. Thereafter, $p_x$ increases again and the cycle repeats. The details of the form of this orbit are given in Appendix B.

The analysis in Appendix B shows that the atom’s average velocity will exhibit a resonant peak whenever $U_M$ just exceeds a local maximum, or falls below a local minimum, in $E'(p_x)$, thus maximizing the time the atom spends in a region of $E'(p_x)$ where $v_x' = dE'(p_x)/dp_x > 0$, and so also maximizing $\langle v_x \rangle = \langle v_x' \rangle_t + v_M$. The minima and maxima in the dispersion curve occur, respectively, at $p_x$ values given by

$$
p_x^{\text{min}} \approx r_{\text{min}} \frac{2\pi \hbar}{d} + \frac{2\hbar^2 v_M}{\Delta d^2},
$$

and

$$
p_x^{\text{max}} \approx -(2r_{\text{max}} - 1) \frac{\pi \hbar}{d} - \frac{2\hbar^2 v_M}{\Delta d^2},
$$

where $r_{\text{min}}$ and $r_{\text{max}}$ are integers ($=1, 2, 3, \ldots$) labeling the minima and maxima, respectively, in $E'(p_x)$. The corresponding critical values of $U_M$, obtained from setting $E'(p_x) = E(p_x) - v_M p_x = \pm U_M/2$, are

$$
U_M^{\text{min}} \approx -2E(p_x^{\text{max}}) + 2v_M p_x^{\text{min}},
$$

and

$$
U_M^{\text{max}} \approx 2E(p_x^{\text{max}}) - 2v_M p_x^{\text{max}}.
$$

The values of $U_M^{\text{max}}$ and $U_M^{\text{min}}$ for $r_{\text{max}}$ and $r_{\text{min}} = 1$ and 2 are shown in Fig. 2 by the labeled arrows and correspond very well with the positions of the resonant peaks in $\langle v_x \rangle_t$.

III. VARIATION OF MOVING LATTICE SPEED

The parameters of a moving optical potential can be varied over a wide range [15,33]. For example, it has been shown that $v_M$ can be increased to $\sim 50$ mm s$^{-1}$ [15] and $U_M$ to $\sim 500$ peV [33].

The color map in Fig. 4 shows the variation of the average velocity of the atom $\langle v_x \rangle$, with both $v_M$ and $U_M$. The figure reveals a complex patchwork of distinct dynamical regimes. At the boundaries between these regimes, the average velocity changes abruptly and may even change sign, indicating that the atom’s response to the moving wave depends critically on both the amplitude and velocity of that wave.

The structure of the color map in Fig. 4 can be understood by considering the transitions between the LD, WD, and BO regimes discussed in the preceding section. The dotted black curve in Fig. 4 shows $U_M^d$ versus $v_M$ [Eq. (6)], marking the transition between the LD and the WD regimes. For $v_M \lesssim 3.5$ mm s$^{-1}$ (i.e., to the left of the intersect between the solid and dotted black curves), increasing $U_M$ across the black dotted curve induces a clear transition from the LD regime, where $\langle v_x \rangle_t \approx 0$ (blue in Fig. 4), to the WD regime, where $\langle v_x \rangle_t \approx v_M$ (yellow or red in Fig. 4).

The black solid curve in Fig. 4 shows $U_M^s$ versus $v_M$ [Eq. (6)], marking the onset of dragged-atom trajectories [Eq. (6)]. The black solid curve shows $U_M^d$ versus $v_M$ [Eq. (7)]. Black dot-dashed curves show $U_M^{\text{min}}$ versus $v_M$ for $r_{\text{min}} = 1, 2$, and 3 (from bottom to top) [Eq. (10)]. Red dot-dashed curves mark values of $U_M^{\text{max}}$ for $r_{\text{max}} = 1, 2$, and 3 (from bottom to top) [Eq. (11)]. The labels LD, WD, and BO mark regions of linear dispersion, wave dragging, and Bloch oscillations.
At this $v_M$ value, the tilt of $E'(p_x)$ is large enough to ensure that the value of $U_M$ needed for the atom to traverse the first local minimum in $E'(p_x)$ is the same as, or larger than, that required to traverse the first local maximum. Therefore, when $U_M \approx U_M^{M}$, the dynamics changes straight from the LD to the BO regime, i.e., without traversing the WD regime.

In the BO regime, we expect the atom to have its highest value of $\langle v_x \rangle$, when $U_M = U_M^{d}$ since here the atom spends most time in the region of the $E'(p_x)$ curve where the gradient of $E'(p_x)$, and thus $v'_x$, is positive. This is confirmed by the color map in Fig. 4, which reveals a narrow region of high $\langle v_x \rangle$ values (red), where $\langle v_x \rangle \sim v_M$, just above the dotted black curve along which $U_M = U_M^{d}$.

Also included in Fig. 4 are black and red dot-dashed curves showing, respectively, $U_M^{\text{max}}$ [Eq. (10)] and $U_M^{\text{min}}$ [Eq. (11)] for $r_{\text{min}}$ and $r_{\text{max}} = 1, 2,$ and $3$. These curves show good correspondence with the positions of $\langle v_x \rangle$, peaks in the color map, which appear as blue-green or yellow stripes for $U_M \gtrsim 40 \text{peV} = 0.390E_R$.

**IV. EFFECT OF INITIAL POSITION**

Equations (6) and (7) indicate that the transitions between distinct dynamical regimes depend on the initial position of the atom $x(t=0) = x_0$. To illustrate this, Fig. 5 shows a color map of $\langle v_x \rangle$ versus $x_0$ and $U_M$ for $v_M = 2.5 \text{mm s}^{-1}$ and, as before, $\lambda_M = 20d$. The color map has an intricate structure, which, we now explain, is associated with the transition between the various dynamical regimes.

The solid curve in Fig. 2 corresponds to a vertical slice through the color map in Fig. 5 when $x_0 = 0$, i.e., along the middle of the five vertical black lines. Increasing $U_M$ along this line induces a transition from the LD into the WD regime on crossing the black dotted curve where $\langle v_x \rangle = v_M$. The WD regime appears as the dark red region in the color map. With a further increase of $U_M$, we enter the BO regime (on crossing the black solid curve), where the color map changes abruptly from red to yellow and the atom’s velocity falls dramatically. Within the BO regime there is a series of resonances, which appear as yellow areas in Fig. 5 and correspond to those arrowed in Fig. 2. As explained in Sec. II and Appendix B, these resonances occur whenever $U_M$ coincides with a local extremum in $E'(p_x)$.

The variation of $U_M^{d}$ with $x_0$ [Eq. (6)], shown by the dotted curve in Fig. 5, agrees well with the transition from the LD to the WD regime seen in the color map. As $x_0$ increases from 0 to $\lambda_M/4$ the transition to the WD regime shifts slowly to lower $U_M^{d}$, which attains a minimum value of $1.3 \text{peV} = 1.27 \times 10^{-2}E_R$ when $x_0 \approx \lambda_M/4$. For $x_0 > \lambda_M/4$, $U_M^{d}$ increases slowly until $x_0 = \lambda_M/2$, at which point the dynamics are approximately equivalent to those at $x_0 = 0$. Conversely, decreasing $x_0$ below 0 makes $U_M^{d}$ increase rapidly until $x_0 \approx -3\lambda_M/16$ when the dotted curve in Fig. 5 diverges. As $x_0$ decreases further, we enter a regime in which there is no transition to the WD regime. When $x_0 \approx -5\lambda_M/16$, the dotted curve reemerges and the value of $U_M^{d}$ decreases rapidly with decreasing $x_0$ until $x_0 = -\lambda_M/2$, which is exactly equivalent to $x_0 = \lambda_M/2$, meaning that the color maps on the left- and right-hand edges of Fig. 5 are identical.

Equation (6) shows that as $v_M$ increases from 0, $U_M^{d}(x_0 = 0)$ also increases and therefore the range of $U_M$ values corresponding to the WD regime is reduced. Figure 5 and Eq. (6) show, in addition, that as $x_0 \rightarrow -\lambda_M/4$, $U_M^{d}(x_0) \rightarrow \infty$, meaning that for any given $v_M$ and $U_M$ the atom will never enter the WD regime. We understand this in the effective dispersion curve picture by noting, from Eq. (5), that when $x_0 = -\lambda_M/4$, $H' = U_M$ and so $E'(p_x)$ can only take values between 0 and $U_M$. Therefore, the atom cannot traverse the local minimum in $E'(p_x)$ when $p_x \approx 0$ [arrowed in Fig. 3(b)] and thus cannot enter the WD regime.

The variation of $U_M^{b}$ with $x_0$ [Eq. (7)], shown by the black solid curve in Fig. 5, is in excellent agreement with the transition from the WD regime (red region in Fig. 5) to the BO regime (above both the black dotted and solid curves in Fig. 5). As $x_0$ increases from 0, $U_M^{b}$ increases until $x_0 \approx 3\lambda_M/16$ where, for the range of $U_M$ shown, there is no transition to the BO regime above the red region. Equation (7) shows that as $x_0 \rightarrow \lambda_M/4$, $U_M^{b} \rightarrow \infty$, implying that trajectories with $x_0 = \lambda_M/4$ are never able to Bloch oscillate for any $v_M$ or $U_M$. Physically this is because when $x_0 = \lambda_M/4$, according to Eq. (5), $E'(p_x)$ only takes values between $-U_M$ and 0, so the atom is unable to traverse the local maximum in $E'(p_x)$ [arrowed in Fig. 3(d)] and thus cannot Bloch oscillate. Figure 5 reveals that the Bloch oscillation regime reappears in the parameter space when $x_0 \approx 5\lambda_M/16$. Thereafter, $U_M^{b}$ (right-hand segment of the black solid curve) decreases with increasing $x_0$ until $x_0 = \lambda_M/2$, which is equivalent to $x_0 = -\lambda_M/2$ (color maps are identical on left- and right-hand edges of Fig. 5).
As \( x_0 \) decreases from 0, the transition from the WD to the BO regime occurs at slowly decreasing \( U_M \) values until \( U_M'(x_0) = U_M''(x_0) \) (where the black dotted and solid curves cross in Fig. 5). As \( x_0 \) decreases further, the two curves cross again when \( x_0 \approx -3\lambda_M/8 \). For \( x_0 \) values between these two crossing points, there is no wave-dragging regime and, for given \( x_0 \), increasing \( U_M \) induces a transition straight from the LD to the BO regime upon crossing the black solid curve. As \( x_0 \) approaches \(-\lambda_M/4\) then, for any given \( U_M \), the atom cannot traverse the local minimum in \( E'(p_x) \) [arrowed in Fig. 3(b)] and thus also does not reach the first local maximum in \( E'(p_x) \) [arrowed in Fig. 3(d)]. Therefore, the atom will only change direction when it reaches the peak in \( E'(p_x) \) occurring when \( p_x \approx -\hbar\pi/d \), resulting in the dramatic change from negative to positive velocity [transition from blue to yellow regions in Fig. 5] when \( U_M \approx 45 \text{ peV} = 0.438E_R \).

As discussed previously, the strong resonant features in \( \langle v_x \rangle \) versus \( U_M \) and \( x_0 \) in Fig. 5 occur when the atom accesses new peaks in \( E'(p_x) \) [see Eqs. (10) and (11)]. The variation of \( U_{\text{min}}' \) and \( U_{\text{max}}' \) with \( x_0 \) shown by the black and red dot-dashed curves, respectively, in Fig. 5 for (from bottom to top) \( r_{\text{min}} \) and \( r_{\text{max}} = 1, 2, \) and 3 agree well with the yellow regions of the color map where \( \langle v_x \rangle \) increases abruptly. Note that near these resonances, the color map changes abruptly between yellow and blue, indicating that \( \langle v_x \rangle \) changes suddenly from positive to negative, i.e., small changes in \( x_0 \) or \( U_M \) switch the atom’s direction of travel.

V. QUANTUM CALCULATIONS

In this section we investigate the full quantum-mechanical description of the semiclassical dynamical regimes revealed in Secs. II–IV. The quantum-mechanical Hamiltonian for the system is

\[
\hat{H} = -\frac{\hbar^2}{2m_a} \frac{\partial^2}{\partial x^2} + V_M(x, t) + V_M(x, t),
\]

where \( m_a \) is the mass of a single \(^{23}\text{Na} \) atom. We solved the corresponding time-dependent Schrödinger equation

\[
i\hbar \frac{\partial \psi(x)}{\partial t} = \hat{H}(x, t)\psi(x)
\]

numerically using the Crank-Nicolson method [35]. Note that we consider the mean-field interaction to be negligible compared with the external potential. This can be realized in experiment by using an applied magnetic field to tune the Feshbach resonance so that the interatomic scattering length is zero. By considering only a noninteracting atom cloud we can present a full and detailed description of the fundamental dynamical phenomena exhibited by the system. If atom interactions are included we expect more complex dynamics, which would deserve further study and analysis.

First, we found the form of the initial wave packet by evolving Eq. (13) in imaginary time using an initial Gaussian wave function with a full width half maximum value \( f_s = 2d \) to produce a state similar to the ground state of an atom cloud held in the SOL by a harmonic trap. To study the atomic dynamics, we then integrated Eq. (13) numerically, using this wave packet as the initial state, which, when \( f_s = 2d \), extends across approximately five wells of the SOL. Figure 6 shows the time evolution of the wave packet in each of the three distinct dynamical regimes corresponding to the semiclassical trajectories shown in Fig. 3 (\( v_M = 2.5 \text{ mm s}^{-1}, \lambda_M = 20d \)) (see also Ref. [36]). The central black curve in Fig. 6(a) corresponds to the semiclassical trajectory in the LD regime \( U_M = 1 \text{ peV}, x_0 = 0 \) shown in Fig. 3(a) and Ref. [36] (movie 1). Also shown are semiclassical trajectories calculated for (from bottom to top) \( x_0 = -2d, -d, 0, d, \) and \( 2d \), i.e., for orbits starting at the centers of the five wells that are spanned by the initial wave function. In this case, most of the wave packet, shown by the grayscale map in Fig. 6(a), does not follow the semiclassical trajectories. Instead, it spreads rapidly with only a small fraction of the wave function being dragged through the lattice.

From Fig. 5, at first sight we might expect that the wave packet lies entirely in the LD regime because, at \( U_M = 1 \text{ peV} = 9.74 \times 10^{-3}E_R \), the vertical lines marking the centers of the potential wells spanned by the wave packet all lie in the light green region below the black dotted curve, i.e., fully within the LD regime. It is clear from Fig. 6(a), however, that the wave packet does not follow a LD semiclassical trajectory. This is because for such a low \( U_M \) value the spreading of the wave packet, resulting from position-momentum uncertainty, dominates the dynamics obtained from the semiclassical analysis. From the uncertainty principle \( f_s \Delta p_x \approx \hbar \), where \( \Delta p_x \) is the spread of the momentum of the wave packet, and the corresponding zero-point energy of the wave packet is \( E_{2p} = \Delta p^2/2m_a \). When \( f_s = 2d, E_{2p} \approx 2.5 \text{ peV} = 2.43 \times 10^{-2}E_R \).
This energy is large enough to allow part of the wave packet to enter the wave-dragging regime, as observed in Fig. 6(a). This zero-point energy determines a lower limit of U_M below which the semiclassical analysis becomes invalid due to being dominated by wave-packet expansion.

Figure 6(b) and Ref. [36] (movie 2) show the evolution of the wave packet when U_M = 10 peV = 9.74 × 10^{-2} E_R, corresponding to the semiclassical trajectory in the WD regime shown in Fig. 3(c). The striking similarity between the semiclassical orbits and the atom density evolution reveals that, in this regime, the wave packet is dragged through the SOL by the MOL. The reason for this is clear from Fig. 5, which reveals that for U_M = 10 peV the full spread of the wave function (between the leftmost and rightmost dashed vertical lines in Fig. 5) lies within the red wave-dragging regime. For this U_M value, the moving lattice is strong enough to dominate any spreading caused by the zero-point energy.

Figure 6(c) and Ref. [36] (movie 3) show the wave-packet evolution for U_M = 150 peV = 1.46 E_R, corresponding to the BO regime [e.g. the orbit in Fig. 3(e)]. The five semiclassical trajectories shown in Fig. 6(c) broadly encompass the evolution of the negative-going part of the wave packet. One might expect that the energy band would break for this large value of U_M, causing the wave packet to no longer track the semiclassical dynamics. However, we note that the relatively long wavelength ∆M = 20d of the moving lattice ensures that the energy drop across a single well within the SOL is ≈ 45 peV = 0.438E_R, which is small enough to keep the band intact. Note also, for high values of U_M, the approximation that the atom will remain in the lowest-energy miniband will become invalid; we estimate this upper limit on U_M by assuming that interband tunneling will occur when the amplitude of the moving wave is approximately equal to the energy gap between the first and second minibands. The two minibands calculated for the stationary optical lattice are ≈ 250 peV apart [see Fig. 1(a)]. Therefore we expect interband tunneling to occur when U_M ≳ 250 peV. It appears, from our numerical simulations, that for U_M ≳ 200 peV = 1.95E_R, the wave-packet dynamics start to deviate from the semiclassical paths due to band breakdown.

The sensitive dependence of the atom dynamics on the initial position x_0, shown in Fig. 5, has an interesting consequence. Namely, if the atom cloud is large enough, it can simultaneously span more than one dynamical regime. For example, in Fig. 6(d) and Ref. [36] (movie 4) we show the wave-packet evolution for U_M = 25 peV = 0.243E_R, with an initial atom cloud width f_x = 8d and center-of-mass position x_0 = 1.5d. The figure shows that the atom cloud splits, with the lower part performing Bloch oscillations around x = 0 and the rest being dragged through the SOL by the MOL. The reason is, as can be seen from Fig. 5, that the upper part of the initial atom cloud with x ≥ 1.5d lies in the wave-dragging regime while the lower part with x ≤ 1.5d is in the Bloch oscillation regime. Our semiclassical analysis suggests that approximately half the cloud is in the wave-dragging regime. This estimate agrees well with the numerical evolution of the wave function, which reveals that after 10 ms, the fraction of the cloud in the wave-dragging regime is 0.495. This result suggests that information about the shape of the initial atom cloud could be obtained by measuring the number of atoms N_U that end up in the upper (dragged) part of the split cloud as a function of x_0. For example, as x_0 increases so that more of the initial wave packet lies within the red WD regime in Fig. 5, i.e., so that the initial wave packet is shifted across the black solid curve, more atoms will end up in the upper part of the split cloud. More quantitatively, we expect that N_U(x_0) ≈ ∫_x = x_0 to ∞ |Ψ(x_0, t = 0)|^2 dx, where x_S satisfies U_M(x_S) = U_M, i.e., marks the position of the solid curve in Fig. 5 for given U_M.

VI. CONCLUSION

We have shown that a periodic optical potential moving through a stationary optical lattice can control the atom orbits in real and momentum space and induce transitions between three distinct dynamical regimes. In a semiclassical picture, the atom can be confined to a small region of the stationary optical lattice dispersion curve, dragged through the stationary optical lattice by the moving wave, or perform Bloch-like oscillations. The crossover between these orbital types creates a rich pattern of transport regimes, with multiple resonances that cause abrupt changes in the magnitude and sign of the atom’s average velocity. These resonances occur whenever there is an abrupt change in the number of Brillouin zones that the atom can access. Since the form of the atom trajectories is predictable and can be tailored by small changes in the MOP parameters, the system provides a mechanism for moving atom clouds between well-defined points in stationary optical lattices. It may also provide a sensitive method to split atom clouds, with potential uses in atom interferometry and in mapping the initial atom cloud dynamically rather than via optical imaging. The dynamics described in this paper are similar to those expected for electrons in acoustically driven superlattices [27]. Consequently, the cold-atom system that we have studied also provides a quantum simulator for acoustically driven semiconductor devices in which the electron orbits are much harder to observe directly.

APPENDIX A: DETAILED DESCRIPTION OF ATOM MOTION IN THE LINEAR DISPERSION REGIME

In the LD regime, initially, for t = 0 and x' = 0, the force applied to the atom by the moving optical lattice is maximal, which makes p_x increase until E'(p_x) = −U_M/2 [lower solid circle in Fig. 3(b)]. At this point, the atom’s velocity in the rest frame v_x = ∂E(p_x)∂p_x + v_M attains its maximum value for the specified initial condition. The potential energy V_M(x') = U_M (to keep H’ constant) is also maximal and so the force is zero in the moving frame. However, in the moving frame x' continues to decrease, which eventually makes the force negative [−dV_M(x')/dx' < 0], thus accelerating the atom in the negative-p_x direction.
The atom continues to move in the negative-$p_x$ direction until $E'(p_x) = U_M/2$ [upper solid circle in Fig. 3(b)] where the atom’s velocity in the rest frame is minimal. The atom then returns to its initial condition with $p_0 = 0$ and the cycle repeats with the atom traversing successive regions where $V_M < U_M/2$ [white regions in Fig. 3(a)] and $V_M > U_M/2$ [gray regions in Fig. 3(a)]. Since the region of the dispersion causing the atom to have nonzero average velocity.

Conversely, the maximum attainable value of $E'(p_x)$ [upper dashed line in Fig. 3(f)] occurs just below the local maximum in $E'(p_x)$, marked by the left-hand bracket in Fig. 3(f), where $V_M$ is maximal. Since the force on the atom is low in this part of the $E'(p_x)$ curve, the atom remains in the negative-velocity region of $E'(p_x)$ [left-hand bracket in Fig. 3(f)] for a long time. This makes the atom take a large jump backward along the $x$ axis [arrows labeled B in Fig. 3(e)]. Figure 3(e) reveals that for $U_M = 150$ peV, the atom jumps backward farther than it jumps forward, thus giving the atom an overall negative average velocity.

APPENDIX B: DETAILED DESCRIPTION OF ATOM MOTION IN THE BLOCH OSCILLATION REGIME

In the BO regime, the atom can access $E'(p_x)$ across several Brillouin zones, which makes $(v_x)_t$ vary in a complex way with increasing $U_M$. For $U_M = 150$ peV = 1.46$E_R$, the lowest possible value of $E'(p_x)$ [lower dashed line in Fig. 3(f)] occurs just below a local minimum in the curve [right-hand arrow in Fig. 3(f)]. The velocity of the atom in the moving frame $dE'(p_x)/dp_x$ is negative at the right-hand solid circle, indicating that the atom is moving in the negative-$x$ direction. However, since $V_M(x')$ is maximal at this point, the moving lattice exerts little force on the atom. Consequently, $p_x$ decreases only slowly and, as a result, the atom also lingers in the region of $E'(p_x)$ where $v'_x$ (and thus $v_x$) is positive [within the region marked by the right-hand bracket in Fig. 3(f)]. Overall, as the atom moves away from the right-hand solid circle in Fig. 3(f), it spends more time with positive than negative velocity causing the atom to jump forward along the $x$ axis [arrows labeled F in Fig. 3(e)].

For $U_M > 150$ peV, the atom jumps backward farther than it jumps forward, thus giving the atom an overall negative average velocity.

If $U_M$ has a value that just exceeds a local maximum or falls just below a local minimum in the $E'(p_x)$ curve, then the time that the atom spends in the region of the $E'(p_x)$ curve, where $dE'(p_x)/dp_x = v'_x > 0$, is maximized. Consequently, the magnitude of the forward jump in the orbit, and therefore $(v_x)_t = (v'_x)_t + U_M$, is maximized. This phenomenon produces the series of peaks observed in the $v_x_t$ versus $U_M$ curve [see arrowed peaks in Fig. 2], the positions of which are discussed in the main text.
