An atom in open space can be detected by means of resonant absorption and reemission of electromagnetic waves, known as resonance fluorescence, which is a fundamental phenomenon of quantum optics. We report on the observation of scattering of propagating waves by a single artificial atom. The behavior of the artificial atom, a superconducting macroscopic two-level system, is in a quantitative agreement with the predictions of quantum optics for a pointlike scatterer interacting with the electromagnetic field in one-dimensional open space. The strong atom-field interaction as revealed in a high degree of extinction of propagating waves will allow applications of controllable artificial atoms in quantum optics and photonics.

A single atom interacting with electromagnetic modes of free space is a fundamental example of an open quantum system (Fig. 1A) [1]. The interaction between the atom (or molecule, quantum dot, et cetera) and a resonant electromagnetic field is particularly important for quantum electronics and quantum information processing. In three-dimensional (3D) space, however, although perfect coupling (with 100% extinction of transmitted power) is theoretically feasible [2], experimentally achieved extinction has not exceeded 12% [3] because of spatial mode mismatch between incident and scattered waves. This problem can be avoided by an efficient coupling of the atom to the continuum of electromagnetic modes confined in a 1D transmission line (Fig. 1B) as proposed in [8–10]. Here we demonstrate extinction of 94% on an artificial atom coupled to the open 1D transmission line. The situation with the atom interacting with freely propagating waves is qualitatively different from that of the atom interacting with a single cavity mode; the latter has been used to demonstrate a series of cavity quantum electrodynamics (QED) phenomena [10–18]. Moreover in open space, the atom directly reveals cavity quantum electrodynamics (QED) phenomena [10–18]. Moreover in open space, the atom directly reveals cavity quantum electrodynamics (QED) phenomena [10–18].

Our artificial atom is a macroscopic superconducting loop, interrupted by Josephson junctions (Fig. 1B) [identical to a flux qubit [24]] and threaded by a bias flux \( \Phi_b \) close to a half flux quantum \( \Phi_0 / 2 \), and shares a segment with the transmission line [22], which results in a loop-line mutual inductance \( M \) mainly due to kinetic inductance of the shared segment [26]. The two lowest eigenstates of the atom are naturally expressed via superpositions of two states with persistent current, \( I_p \), flowing clockwise or counterclockwise. In energy eigenbasis the lowest two levels \( |g \rangle \) and \( |e \rangle \) are described by the truncated Hamiltonian \( H = \hbar \omega_a \sigma_z / 2 \), where \( \omega_a = \sqrt{\omega_0^2 + \varepsilon^2} \) is the atomic transition frequency and \( \sigma_z (i = x, y, z) \) are the Pauli matrices. Here, \( \hbar c = 2I_p \delta \Phi \) (\( \delta \Phi = \Phi_b - \Phi_0 / 2 \)) is the energy bias controlled by the bias flux, and \( \hbar \omega_0 \) is the anticrossing energy between the two persistent current states. The excitation energies of the third and higher eigenstates are much larger than \( \hbar \omega_a \); therefore they can be neglected in our analysis.

We considered a dipole interaction of the atom with a field of an electromagnetic 1D wave. In the semiclassical approach of quantum optics, the external field of the incident wave \( I_0(x,t) = I_0 e^{i k x - i \omega t} \) (where \( \omega \) is the frequency and \( k \) is the wavenumber) induces the atomic polarization. The atom with characteristic loop size of ~10 \( \mu m \) (which is negligibly small as compared with the wavelength \( \lambda \sim 1 \) cm) placed at \( x = 0 \) generates waves \( I_{sc}(x,t) = I_{sc} e^{i k |x| - i \omega t} \), propagating in both directions (forward and backward). The current oscillating in the loop under the external drive induces an effective magnetic flux \( \phi \) (playing a role of atomic polarization). The net wave \( I(x,t) = (I_0 e^{i k x} + I_{sc} e^{i k |x|}) e^{-i \omega t} \) satisfies the 1D wave equation \( \partial_x^2 I - v^{-2} \partial_t I = c \delta(x) \partial_t \phi \), where the wave phase velocity is \( v = 1 / \sqrt{\varepsilon c} \) (\( l \) and \( c \) are indistinguishable and capacitance per unit length, respectively) and the dispersion relation is \( \omega = \nu k \).

At the degeneracy point (\( \varepsilon = 0 \)), \( \omega_a = \omega_0 \), and the dipole interaction of the atom with the electromagnetic wave in the transmission line \( H_{int} = -\phi_p \text{Re}[I_0(0,t) \sigma_z] \) is proportional to the dipole moment matrix element \( \phi_p = M I_p \). In the rotating wave approximation, the standard form of the Hamiltonian of a two-level atom interacting with the nearly resonant external field is \( H = -(\hbar \delta \omega \sigma_z + \hbar \Omega \sigma_x) / 2 \). Here \( \delta \omega = \omega - \omega_0 \) is the detuning and \( \hbar \Omega = \phi_p I_0 \) is the dipole interaction energy. The time-
dependent atomic dipole moment can be presented for a negative frequency component as $\langle \phi(t) \rangle = \phi_0 (\sigma^-) e^{-i\omega t}$, and the boundary condition for the scattered wave generated because of the atomic polarization satisfies the equation $2i\hbar (I_{sc}/2) = -\omega^2 c \phi_0 (\sigma^-)$, where $\sigma^\pm = (\sigma_x \pm i\sigma_y)/2$. Assuming that the relaxation of the atom is caused solely by the quantum noise of the open line, we obtain the relaxation rate $\Gamma_1 = (\hbar \omega_0^2)/(\hbar^2 Z)$ (where $Z = \sqrt{\hbar/c}$ is the line impedance) and find

$$I_{sc}(x,t) = \frac{i\hbar \Gamma_1}{\phi_0} \langle \sigma^- \rangle e^{i(k|x| - i\omega t)}.$$  \hspace{1cm} (1)

This expression indicates that the atomic dissipation into the line reveals itself even in elastic scattering.

The atom coupled to the open line is described by the density matrix $\rho$, which satisfies the master equation $\dot{\rho} = -\frac{i}{\hbar} [H, \rho] + \hat{L}[\rho]$. At zero temperature, the simplest form of the Lindblad operator $\hat{L}[\rho] = -\Gamma_1 \sigma_z \rho_{ee} - \Gamma_2 (\sigma^+ \rho_{eg} + \sigma^- \rho_{ge})$ describes energy relaxation (the first term) and the damping of the off-diagonal elements of the density matrix with the dephasing rate $I_{dc} = \Gamma_1/2 + \Gamma_\varphi$ (the second term), where $\Gamma_\varphi$ is the pure dephasing rates. It is convenient to define reflection and transmission coefficients $r$ and $t$ according to $I_{sc} = -r I_0$ and $I_0 + I_{sc} = t I_0$, and, therefore, $t = 1 - r$. From Eq. 1 we find the stationary solution

$$r = r_0 \frac{1 + i\delta \omega/\Gamma_2}{1 + (\delta \omega/\Gamma_2)^2 + \Omega^2/\Gamma_1 \Gamma_2},$$  \hspace{1cm} (2)

where the maximal reflection amplitude $r_0 = \eta \Gamma_1/2 \Gamma_2$ at $\delta \omega = 0$. Here $\eta$ presents dimensionless coupling efficiency to the line field, including non-radiative relaxation. The maximal possible power extinction $(1 - |t|^2)$ can reach 100% when $|r_0| = 1$. It takes place for $\eta = 1$ and $\Gamma_2 = \Gamma_1/2$, that is, in the absence of pure dephasing, $\Gamma_\varphi = 0$. In such case, the wave scattered forward by the atom is canceled out because of destructive interference with the incident wave ($I_{sc} = -I_0$). Although Eq. 2 is obtained for the degeneracy point ($\epsilon = 0$), it remains valid in the general case of $\epsilon \neq 0$ if the dipole interaction energy $\hbar \Omega$ is multiplied by $\omega_0/\omega_i$.

The excitation energy of the atom was revealed by means of transmission spectroscopy (Fig. 1C). Owing to the broadband characteristics of the transmission line, we swept the frequency of the incident microwave in a wide range and monitored the transmission. As shown in the inset of Fig. 1C, the resonance is detected as a sharp dip in the power transmission coefficient $|t|^2$. At resonance, the power extinction reaches its maximal value of 94%, which suggests that the system is relatively well isolated from other degrees of freedom in the surrounding solid-state environment and behaves as a nearly isolated atom in open space, coupled only to the electromagnetic fields in the space. The resonance frequency $\omega_0$ is traced as a function of the flux bias $\delta \Phi$. By fitting the data, we obtained $\omega_0/2\pi = 10.204$ GHz at $\delta \Phi = 0$ and the persistent current $I_p = 195$ nA.

The elastic response of the artificial atom shows typical anomalous dispersion. Figure 2A represents the reflection coefficient derived from the transmission according to $r = 1 - t$ and obtained at $\delta \Phi = 0$. Similarly to the case of a natural atom, we can define the polarizability $\alpha = \alpha' + i\alpha''$ where $\alpha = (\sigma_z + i\sigma_y)/2$. Assuming that the relaxation of the atom is caused solely by the quantum noise of the open line, we obtain the relaxation rate $\Gamma_1 = (\hbar \omega_0^2)/(\hbar^2 Z)$ (where $Z = \sqrt{\hbar/c}$ is the line impedance) and find

$$I_{sc}(x,t) = \frac{i\hbar \Gamma_1}{\phi_0} \langle \sigma^- \rangle e^{i(k|x| - i\omega t)}.$$  \hspace{1cm} (1)

This expression indicates that the atomic dissipation into the line reveals itself even in elastic scattering.
experimentally, it may be reasonable because (i) all the line current should effectively interact with the atom and (ii) the possible relaxation without emission measured for isolated atoms is weak being typically less than $10^6$ s$^{-1}$ [28]. In a case of imperfect coupling ($\eta < 1$) the actual $\Gamma_1$ could be slightly higher.

The nonlinearity of the atom manifests in the saturation of the atom excitation. With increasing the power of the incident microwave $W_0$, $|r|$ monotonically decreases, and in the Smith chart (Fig. 2B) the shape of the trajectory changes from a large circle to a small ellipse. As a single two-level system, the atom is saturated at larger powers and can have large reflectance only for the weak driving case. Again, the nearly perfect agreement between the calculations and the measurements supports our model of a two-level atom coupled to a single 1D mode. Any artificial medium built of such “atoms” [29] will also have a strongly nonlinear susceptibility.

So far we have investigated elastic Rayleigh scattering in which the incident and the scattered waves have the same frequency. However, the rest of the power $W_{sc}' = W_0 (1 - |t|^2 - |r|^2)$ is scattered inelastically and can be observed in the power spectrum. The spectrum was measured at the degeneracy point ($\delta \Phi = 0$) under a resonant drive with the power corresponding to $\Omega/2\pi \approx 57$ MHz (Fig. 3A). It manifests the resonance fluorescence triplet, also known as the Mollow triplet [19–23]. In the case of a strong driving field ($\Omega^2 \gg \Gamma_0^2$), the expression for the inelastically scattered power simplifies to $W_{sc}' \approx (\Gamma_0^2/\Omega^2) W_0$, which is independent of the incident power and can be rewritten as $W_{sc}' \approx h\omega \Gamma_1/2$. The atom is half populated by the strong drive and spontaneously emits with rate $\Gamma_1$. Assuming $\eta = 1$, the spectral density measured in one of the two directions is expected to be

$$S(\omega) \approx \frac{1}{2\pi} \frac{\hbar\omega \Gamma_1}{8} \left( \frac{\gamma_s}{\delta\omega + \Omega^2} + \frac{2\gamma_c}{\delta\omega^2 + \gamma_c^2} \right),$$

where half-width of the central and side peaks are $\gamma_c = \Gamma_2$ and $\gamma_s = (\Gamma_1 + \Gamma_2)/2$, respectively. The red curve in Fig. 3A is drawn by using Eq. 3 without any fitting parameters. The good agreement with the theory indicates the high collection efficiency of the emitted photons, which is due to the 1D confinement of the mode. The shift of the side peaks, $\pm \Omega$, from the main resonance depends on the driving power. The intensity plot in Fig. 3B shows how the resonance fluorescence emission depends on the driving power. The dashed white lines mark the calculated position of the side peaks as a function of the driving power, showing good agreement with the experiment.

The demonstrated resonance wave scattering from a macroscopic “artificial atom” in an open transmission line, indicates that such superconducting quantum devices can be used as building blocks for controllable, nonlinear interactions.
quantum coherent macroscopic artificial structures, in which a plethora of effects can be realized from quantum optics of atomic systems. Material and Methods

S1. Sample design and fabrication

The coplanar transmission line with a characteristic impedance $Z \simeq 50 \Omega$ is made by patterning a gold film deposited on a silicon substrate. In the middle of the chip the central conductor of the waveguide is narrowed and replaced by aluminium. The latter is deposited together with the artificial atom, using shadow evaporation. The experiment is performed in a dilution refrigerator at a temperature of 40 mK.

S2. Transmission and reflection coefficients of the elastic scattering

We measure the complex transmission and reflection coefficients, $t$ and $r$, by a phase-sensitive vector network analyzer. The transmission characteristics of the microwave line are calibrated with the artificial atom effectively removed: It is offset by a dc flux bias such that its transition frequency does not fall in the measurement frequency range. By comparing the transmitted and reflected powers we verify that the relation $|1 - t| = |r|$ holds with an accuracy less than 5%. However, the reflection coefficient $r$ presented in the text is calculated from measured $t$ by using the relation $r = 1 - t$, because the phase of the weak reflected wave is not easy to calibrate. Schematic diagram of the experimental setup for measuring the coherent transmission and reflection coefficient is presented in Fig. S1A. For transmission and reflection measurements we use two different input lines and a single output line.

S3. Spectrum of the inelastic scattering

To measure weak resonance fluorescence emission on the background of the amplifier noise, we modulate the excitation power and use digital differentiation. The noise spectral density of the preamplifier placed at 4 K is $2 \pi S(\omega) = k_B T_n \simeq 1.9 \times 10.22$ W/Hz, which corresponds to the effective noise temperature of the amplifier at the sample $T_n = 14 K$. A narrow elastic scattering peak at zero detuning, with a width determined by the 1-MHz resolution bandwidth of the spectrum analyzer, is eliminated by analog cancelation using destructive interference and additional digital filtering. In Fig. S1B, the schematic diagram of the setup for measuring the resonance fluorescence spectrum is presented.
