(Received 7 March 2010; accepted 30 August 2010; published online 27 October 2010)

We model the effects of an internal wave on the structure of the oceanic subsurface bubble layer, generated by breaking surface waves. We consider two situations: when breaking is caused either by a strong sustained wind or by the direct interaction of surface waves with an internal wave. We find that the effects are twofold; bubbles are driven by the internal wave field and the injection of bubbles into the water is enhanced in downwelling areas behind the crests of the internal wave. We use an uncoupled problem formulation, substituting the solution for an internal wave in a two-layer fluid model into the equations describing the bubble dynamics. The latter equations are solved numerically, showing structure formation in the bubble layer for each of the two cases, when one of the aforementioned mechanisms dominates the other. © 2010 American Institute of Physics. [doi:10.1063/1.3499379]

I. INTRODUCTION

It is well-known that breaking surface waves injects bubbles into the subsurface layer of the ocean. For winds exceeding 6.5–7 m/s, there is a continuous bubble layer of variable thickness, which may extend to a depth of several meters beneath the surface.1–5 The observed bubble layer is highly structured, varies both spatially and temporally, and depends significantly on wind speed. In general, there is a monotonic decrease in the bubble void fraction with increasing depth. The void fraction profile either decays exponentially, with a typical e-folding scale of order 1 m, which depends on the wind speed (see Ref. 6) or it may follow an inverse-square profile.7 The volume-scaled representation of the number density of bubbles as a function of the bubble radius has a peak at all depths and decreases rapidly on either side of the peak and also rapidly with depth (see, e.g., Refs. 5 and 8–10 and the references therein). These observations have shown that bubbles with radii of approximately 50–100 μm contribute most to the total void fraction, except very close to the surface.3

Recent observations of the structure of the bubble layer (e.g., Refs. 2, 5, and 10) and developments in the mechanics of multiphase media (e.g., Refs. 11–14), have allowed us to begin the consideration of the effect of bubbles on internal waves.15–17 Our results indicated that bubble distributions, when present, can have a profound effect on the structure of the internal wave field (but do not significantly affect the surface wave mode). Bubbles can support their own “bubble” modes of internal waves, even in an otherwise homogeneous fluid. If there is a background density stratification which is present in the absence of any bubbles, supporting one or more internal modes, then the weak coupling introduced through the interaction of the two waveguides induces a splitting of the dispersion curves, which is reflected in the behavior of the respective modal functions. In the simple case when the background density stratification (in the absence of bubbles) is modeled by a two-layer fluid so that there is just a single pycnocline mode, the splitting of the dispersion curves is most pronounced for a shallow pycnocline and a relatively large void fraction for the bubbles compared to the density jump across the interface. Otherwise, for a deeper pycnocline, for a larger density jump across the pycnocline, or for a smaller void fractions of bubbles, the splitting of the dispersion curves is still present, but is less pronounced, resulting in a pycnocline mode which has a similar structure to the bubble modes. Finally, if the pycnocline is well separated from the bubble layer, then there is virtually no interaction between the pycnocline mode and the bubble modes and we have two independent waveguides located at different depths.

This present study is devoted to the opposite problem of the effects that an internal wave might have on the subsurface bubble layer. There are some observations of such effects in the ocean,18–20 which motivate this study. We consider an uncoupled problem formulation, where we look at the dynamics of a bubble layer in the presence of a specified internal wave field, modeled as an interfacial wave in a two-layer fluid. This representation for the internal wave field is substituted into the equation describing the bubble dynamics (similar to Refs. 2 and 7–9 in the studies of the steady-state distributions), which are then solved numerically to reveal the structure formation in the bubble layer. We consider two

cases. In the first case, the bubbles are injected by breaking surface waves generated by a strong wind and this is represented by a source term which is spatially homogeneous in the horizontal direction. In the second case, the surface waves are directly modulated by the internal wave, leading to a source of bubbles which is spatially inhomogeneous in the horizontal direction; here we adapt and develop an approach of Baschek et al. to model this situation. Since bubbles significantly affect the acoustic properties of a fluid, we illustrate some consequences of the described physical effects by calculating, along with hydrodynamic characteristics such as the bubble void fraction, the acoustic wave speed in the mixture and the scattering intensity. Some relevant acoustic data are available in Refs. 19 and 20.

Our paper is set out as follows. Section II describes the problem formulation used to model the structure formation in the bubble layer in the presence of an internal wave. The numerical scheme is described in Sec. III. In Sec. IV, we first consider the case when the bubble layer is supported by a sustained strong wind when we assume that the source of bubbles from the surface on average is homogeneous in the horizontal direction, while it is decaying in the vertical direction. In Sec. V, we consider a second case, when the wind is weak, and instead the bubble layer is supported by the interaction of surface waves with an internal wave propagating along a shallow pycnocline; the bubble source term is now highly inhomogeneous in the horizontal direction, as well as decaying in the vertical direction. We conclude in Sec. VI, comparing the qualitative predictions of our study with some existing observations. The solution for an internal wave in a two-layer fluid is briefly overviewsed in Appendix A. A summary of some theoretical results related to the steepening of surface waves due to their interaction with an internal wave is given in Appendix B.

II. PROBLEM FORMULATION

The internal wave field constitutes a fundamental component of the ocean and is a subject of active research (for example, see Refs. 22–25). For sufficiently large horizontal scales, it is customary to reduce the study of internal waves to a normal mode structure with associated horizontal propagation features (e.g., Refs. 26–28).

In this paper, we aim to model the structure formation in the bubble layer due to an internal wave propagating along a sharp pycnocline (see Fig. 1). We consider a two-dimensional problem formulation and use the spatial coordinates $(x,z)$, where $x$ is horizontal and $z$ is vertical. The undisturbed free surface is at $z=0$. We use the well-known model of a two-layer fluid (see Appendix A), where we have just one pycnocline mode in the absence of any bubbles. Note that this situation changes if we also take account of the depth-dependent bubble distribution when we have infinitely many new modes supported by the bubbles (see Ref. 17).

To describe the temporal and spatial concentration of bubbles in the fluid we extend the work of Thorpe and Buckingham and use the model

$$
\frac{\partial N}{\partial t} + \frac{\partial}{\partial x}(Nu) + \frac{\partial}{\partial z}(Nv) = \frac{\partial}{\partial x}\left(K_v \frac{\partial N}{\partial x}\right) + \frac{\partial}{\partial z}\left(K_z \frac{\partial N}{\partial z}\right) - \alpha N + q(x,z,t). \tag{1}
$$

Here, $N$ is the number density of bubbles, $K_v$ is the turbulent diffusion coefficient, $\alpha$ is the dissolution rate (assumed to be constant), $q(x,z,t)$ is the source of bubbles injected through the surface, $u$ is the horizontal velocity of bubbles, which coincides with the horizontal velocity of the fluid [given approximately by formulae (A7) and (A10) in Appendix A], and $v$ is the vertical velocity of bubbles, related to the vertical velocity of the fluid [given approximately by formulae (A8) and (A11) in Appendix A] by

$$
u = w + v_w,$$

where, following Ref. 8, we use the relations

$$
v_w = \frac{2\alpha^2 g \rho_l}{9 \mu_l} [(y^2 + 2y)^{1/2} - y], \quad y = 10.82\frac{\mu_l^2}{\rho_l^2 g a^2}
$$

for the rise speed of bubbles with respect to the fluid at equilibrium. Here, $\mu_l$ is the coefficient of dynamic viscosity of the fluid, $a$ is the bubble radius, and $g$ is gravity. Equation (1) describes the evolution of $N$ in time and space caused by convection [second and third terms in the left hand side of Eq. (1)], turbulent diffusion (first and second terms in the right-hand side), dissolution $\alpha N$, and source $q(x,z,t)$.

In Eq. (1), $q(x,z,t)$ is a number density of bubbles injected through the surface to any depth in unit time. When the bubble layer is supported by a strong sustained wind, we will model the source of bubbles by a horizontally and temporally homogeneous source in a thin surface layer, which we represent simply as $q_0 \delta(z+e), 0 < e < H$ (see Sec. IV). However, this situation becomes invalid in the case when breaking is caused primarily by the steepening of surface waves due to interaction with an internal wave, propagating close to the sea surface. Indeed, in this case we can no longer assume the bubble layer to be horizontally and temporally homogeneous. In Sec. V, we find an expression for the source term, following Ref. 21. In both cases, the source term is confined to a very thin layer near the surface when compared to the resulting depth-dependent bubble distribution and it is then convenient to replace the source term in Eq. (1) with a surface flux condition.

FIG. 1. Problem formulation: A two-layer fluid with a subsurface bubble layer.
For the case of a bubble layer supported by a strong sustained wind, when \( q(x,z,t) = q_0 \delta(z+e) \), the right-hand side of Eq. (2) reduces to just \( q_0 \). Since \( N \) quickly decreases with depth, the bottom condition does not affect the solution noticeably; here we use the zero flux \( \partial N / \partial z = 0 \) condition at \( z = -H \).

Let us suppose that the majority of bubbles have almost equal size, which depends on values of \( x, z, \) and \( t \), i.e., \( a = a(x,z,t) \). The bubble radius can be found from the equation for the change of the bubble mass due to dissolution (similar to Ref. 2)

\[
\frac{d}{dt_b} \left( \frac{4 \pi \rho_g a^3}{3} \right) = -4 \pi aD \kappa (p_g - p) N_u,
\]

where

\[
\frac{d}{dt_b} = \frac{\partial}{\partial t} + \left( u - \frac{K_v}{N} \frac{\partial N}{\partial x}\right) \frac{\partial}{\partial x} + \left( v - \frac{K_v}{N} \frac{\partial N}{\partial z}\right) \frac{\partial}{\partial z}
\]

is the full derivative with respect to time for the bubble field. Here, \( \rho_g \) is the gas density in a bubble, \( D \) is the molecular diffusion coefficient, \( p \) is the pressure in the fluid [given by formulae (A9) and (A12) in Appendix A], \( Nu \) is the Nusselt number, related to the Peclet number (Pe) by

\[
Nu = \frac{2}{\pi} \frac{Pe}{L}, \quad \text{where} \quad Pe = \frac{aw}{D},
\]

and \( \kappa \) is the absorption coefficient, relating the pressure in the fluid to the volume concentration of the dissolved gas \( C_v = \kappa p \).

Then, the pressure in the gas is found from the quasi-static relation (e.g., Ref. 14)

\[
p_g = p + 2\sigma a,
\]

where \( \sigma \) is the surface tension coefficient. Finally, the gas density in a bubble is found from the equation

\[
\frac{d}{dt_b} \left( \frac{p_g}{\rho_g} \right) = 0
\]

for temperature conservation in the ideal gas (see Ref. 17).

Thus, for a given internal wave field in the fluid, substituting expressions for \( u(x,z,t), w(x,z,t), \) and \( p(x,z,t) \) into Eqs. (1), (3), and (4), we can describe the dynamics of the bubble layer in the internal wave field. We impose constant boundary conditions for the radius and the gas density at the surface \( z = 0 \)

\[
a(x,0,t) = a_0, \quad \rho_g(x,0,t) = \rho_{g0}
\]

and zero flux conditions at \( z = -H \). Other boundary conditions, constants, and numerical schemes are discussed in the following sections.

### III. NUMERICAL SCHEME

In the sequel, the governing Eqs. (1), (3), and (4) are solved by a first order implicit numerical scheme, which is based on the finite volume method,\textsuperscript{20} \( \Omega = \{(x,z): 0 \leq x \leq L, \quad -H \leq z \leq 0 \} \), with length \( L \) equal to the internal wavelength \( \lambda \) and depth \( H \) taken to be twice the pycnocline depth \( h \).

At a given time step \( t_n \), we first obtain the gas density \( \rho_g(x_i,z_j,t_n) \) from Eq. (4), then we get the bubble radius from Eq. (3), and finally we obtain \( N(x_i,z_j,t_n) \), solving Eq. (1). Here we show the finite volume discretization of Eq. (1) [Eqs. (3) and (4) are written similarly]

\[
\frac{N^{n+1}_{ij} - N^n_{ij}}{\Delta t} = \frac{1}{\Delta x} (u^{n+1}_{i+1/2,j} - u^{n+1}_{i-1/2,j}) N^{n+1}_{ij} + \frac{1}{\Delta z} [\max(u^{n+1}_{i-1, j+1/2}, 0) - \min(u^{n+1}_{i+1, j-1/2}, 0)] N^{n+1}_{ij} + \frac{1}{\Delta x} \min(u^{n+1}_{i+1, j-1/2}, 0) N^{n+1}_{ij}
\]

\[
- \frac{1}{\Delta x} \max(u^{n+1}_{i-1, j+1/2}, 0) N^{n+1}_{i-1,j} + \frac{1}{\Delta z} (v^{n+1}_{i,j+1/2} - v^{n+1}_{i,j-1/2}) N^{n+1}_{ij} + \frac{1}{\Delta z} [\max(v^{n+1}_{i,j-1, 2}, 0) - \min(v^{n+1}_{i,j+1, 2}, 0)] N^{n+1}_{ij}
\]

\[
+ \frac{1}{\Delta z} \min(v^{n+1}_{i,j+1, 2}, 0) N^{n+1}_{ij} - \frac{1}{\Delta z} \max(v^{n+1}_{i,j-1, 2}, 0) N^{n+1}_{ij} - \frac{1}{\Delta z} \max(v^{n+1}_{i,j+1, 2}, 0) N^{n+1}_{ij} + \frac{1}{\Delta z} \min(v^{n+1}_{i,j+1, 2}, 0) N^{n+1}_{ij}
\]

\[
= \frac{1}{\Delta x} (K_{v,i+1/2,j} N^{n+1}_{i+1,j} - N^{n+1}_{i,j}) - K_{v,i-1/2,j} N^{n+1}_{i-1,j} - K_{v,i+1/2,j} N^{n+1}_{i-1,j} - K_{v,i-1/2,j} N^{n+1}_{i+1,j} - \sigma \frac{\partial}{\partial x} N^{n+1}_{ij}.
\]

The numerical solution is obtained by an iterative procedure until convergence. We imposed periodic boundary conditions at \( x = 0 \) and \( x = L \)

\[
N(0,z,t) = N(L,z,t), \quad a(0,z,t) = a(L,z,t), \quad \rho_g(0,z,t) = \rho_g(L,z,t).
\]
IV. STRONG WIND: INTERNAL WAVE MODIFICATION OF THE BUBBLE LAYER

According to experimental observations (see Ref. 1), surface waves start to break at wind speeds of about 2–3 m/s, and in winds of about 7 m/s, the bubbles form a continuous layer just below the surface. Here we consider the formation of the bubble layer at high wind speeds, when the source at the surface can be treated as homogeneous and, as discussed above, we use a simple model $q(x, z, t) = q_0(z + e)$ where $q_0$ is a constant.

To model structure formation in the bubble layer, we choose the following parameters of the computational domain: $L = \lambda = 200$ m, $h = 10$ m, and $H = 20$ m. Following Ref. 2, we take $\mu = 10^{-3}$ Pa s, $\sigma = 0.036$ N/m, $D = 2 \times 10^{-9}$ m$^2$/s, and $\kappa = 2.1 \times 10^{-7}$ kg/(m$^3$ Pa), while $\rho_1 = 999$ kg/m$^3$ and $\rho_2 = 1000$ kg/m$^3$. We assume that at the surface, $a_0 = 50$ $\mu$m and $\rho_{g0} = 1.2(1 + 2\sigma/p_0 \alpha_0)$ kg/m$^3$, where $p_0 = 10^5$ Pa is the atmospheric pressure. The coefficient of turbulent diffusion $K_v$ is taken in the form

$$K_v = K_{v0} - c_k \sqrt{\frac{\rho_0 c_d}{\rho_1}} W z,$$

where $c_k = 0.4$ is the Von Karman constant, $c_d = 1.3 \times 10^{-3}$ is the drag coefficient, $\rho_{g0}$ is the gas density at the surface, $W$ is the wind speed, and $K_{v0}$ is the turbulent diffusion coefficient at the interface

$$K_{v0} = - c_k \sqrt{\frac{\rho_0 c_d}{\rho_1}} W z.$$

In our calculations, we use $z_s = -1.5$ m, so formula (6) gives $K_v = 5.2 \times 10^{-4}(1.5 - z) W$.

Following Ref. 30, we consider $q_0$ in the form $q_0 = \hat{q}_0(W/10)^{1/2}$, where $\hat{q}_0$ is the source term value for $W = 10$ m/s and $\eta$ is an unknown parameter. The source term $\hat{q}_0$ and the dissolution rate $\alpha$ in Eq. (1) can be estimated as follows. Let us suppose that for $W = W_0$, the void concentration changes exponentially with depth according to the empirical law

$$\hat{\alpha}_g = \hat{\alpha}_{g0} \exp(z/0.7),$$

where $\hat{\alpha}_{g0} = 10^{-5}$, which is in good agreement with experimental data (see Refs. 7 and 10, for instance). From Eqs. (1) and (2), the depth-dependent number distribution $\hat{N} = \hat{N}(z)$ of bubbles is described by the following problem:

$$\frac{d}{dz} \left[ K_v \frac{d\hat{N}}{dz} - \frac{\sigma_c \hat{N}}{dz} \right] - \sigma_s \hat{N} = 0,$$

$$K_{v0} \frac{d\hat{N}}{dz} - \frac{\sigma_c \hat{N}}{dz} \bigg|_{z = 0} = \hat{q}_0,$$

where we simplified the problem by assuming infinite depth, which is clearly a good approximation. Following the analysis of Buckingham, the solution to this problem is

$$\hat{N}(z) = \hat{N}(0) F(z), \quad \hat{N}(0) \left[ K_{v0} \frac{dF(0)}{dz} - \frac{\sigma_c \hat{N}}{dz} \right] = \hat{q}_0,$$

where

$$F(z) = \frac{\xi(z)^{-2} K_v[\xi(z)]}{\xi(0)^{-2} K_v[\xi(0)]},$$

$$\xi(z) = \frac{2 \sigma_v (K_{v0} - \alpha)}{\alpha},$$

$$\alpha = c_k \sqrt{\frac{\rho_0 c_d}{\rho_1}} W z, \quad \nu = \frac{\nu_s}{\alpha}.$$

Here $K_v(\cdot)$ is the modified Bessel function of the second kind. This then determines $\hat{q}_0$ in terms of $\hat{N}(0)$. Note that in the limit $\nu \to \infty$ with $z$ fixed, that is we let $\alpha \to 0$, the solution (8) reduces to

$$F(z) = \exp \left[ \nu_s + \frac{2 \sigma_v}{2 K_{v0} \sigma_s} \right],$$

$$\hat{N}(0) = \frac{2 \hat{q}_0}{\nu_s + 2 K_{v0} \sigma_s - \nu_s}.$$

When applicable, this expression is much easier to use in practice than Eq. (8). For instance, assuming that all bubbles close to the surface have an approximately constant radius $a = a_0 = \text{const}$ and the given void fraction $\hat{\alpha}_{g0} = \frac{4}{3} m \hat{N}(0) a_0^3$, which is proportional to $\hat{N}(0)$, formulae (7) and (9) allow some simple estimates of $\hat{q}_0$ and $\sigma_s$.

Next to find $\eta$ we use the empirical formula

$$d = 0.4(W - 2.5),$$

where $d$ (meters) is an average penetration depth of the bubble clouds (may be treated as the depth at which void concentration equals to void concentration for $W = 2.5$ m/s at the surface). Solving Eq. (1) as above for an undisturbed fluid for different values of $W$ we found that the best approximation of Eq. (10) is achieved for $\eta = 3$, which is the same as obtained in Ref. 30.

Figure 2 shows the distributions of the acoustic speed, number density of bubbles, their radii, and void fraction for a pure two-layer fluid periodic internal wave of amplitude $3$ m and for a wind speed $10$ m/s. The internal wave propagates from left to the right. The speed of sound in the fluid with gas bubbles is calculated according to the following formula (e.g., Ref. 14):

$$c^2 = \frac{\rho_0 c^2 + (1 - \rho_0) \rho_1 c^2}{[\alpha_s \rho_s + (1 - \alpha_s) \rho_0]\alpha_s \rho_s c^2 + (1 - \alpha_s) \rho_0 c^2]}$$

where $c_0 = 290$ m/s and $c_0 = 1500$ m/s are the values of sound speed in a gas and a fluid. The numerical calculations were carried out on a homogeneous grid with 40 cells in the horizontal and 80 cells in the vertical direction. The initial conditions correspond to undisturbed fluid. The graphs are plotted for the time $t = 10T$, where $T$ is the period of the internal wave, for which the numerical solution becomes strictly periodic.
Our results show that the periodic internal wave produces a displacement in the surrounding fluid with orbital velocities up to 5–10 cm/s. Some bubbles move toward the interface and others are carried down by the flow. Consequently, we observe horizontally inhomogeneous profiles of the bubble parameters not only in the neighborhood of the pycnocline, but also away from it. For a fixed depth the void fraction of bubbles shows a considerable horizontal variability, being at maximum in the downwelling area behind the crest of the internal wave. It is necessary to note, however, that in this current study we have neglected the effects of Langmuir circulation, which can also contribute significantly to the organization of bubbles (e.g., Refs. 32–34). Nevertheless, we believe the mechanism described in this paper to be dominant at least in the cases when the average distance between windrows is much smaller than the wavelength of the internal wave or when the internal wave has a large amplitude.

Figure 3 shows the distributions of acoustic speed and void fraction for the wind speeds $W=7.5$ m/s and $W=12.5$ m/s. Since the turbulent diffusion coefficient and the value of gas volume fraction at the surface depend on the wind speed, the penetration of bubbles increases and the horizontal inhomogeneities become more evident with the increase of $W$.

Figure 4 shows the log($M_v$) distribution for $W=7.5$ m/s and $W=12.5$ m/s. Here $M_v$ is the acoustic scattering cross section per unit volume (e.g., Ref. 2)

$$M_v = N \sigma_v, \quad \sigma_v = \frac{4 \pi a^2}{[(\omega_0/\omega)^2 - 1]^2 + \Psi^2},$$

where

$$\Psi = \frac{3 \rho_c \epsilon_s^2}{a \rho_c c_g \omega}, \quad \omega_0 = \frac{\sqrt{3} \xi_s}{2 \pi a},$$

and $\omega=600$ kHz is the typical sonar frequency. Similar to the other parameters, the horizontal distribution of log($M_v$) in the subsurface layer approximately copies the pycnocline wave with a shift to the right (in the direction of the internal wave propagation).
FIG. 3. (Color online) (Top row) Acoustic speed (meters per second) and (bottom row) void fraction for a two-layer periodic internal wave of 3 m amplitude shown in (a) for a wind speed (a) \( W = 7.5 \) m/s and (b) \( W = 12.5 \) m/s.

FIG. 4. (Color online) Logarithm of the scattering intensity \( M_r \) (measured in units \( m^{-1} \)) for a two-layer fluid periodic internal wave of 3 m amplitude for two values of a wind speed \( W = 7.5 \) m/s and \( W = 12.5 \) m/s.
In Fig. 5, the time variations of the acoustic speed \( c \) and scattering intensity \( \log(M_s) \) are displayed for \( W=10 \) m/s and three different depths: \( z=-0.5 \) m, \( z=-1 \) m, and \( z=-3 \) m.

The character of the distribution of bubbles in the subsurface layer depends on the parameters of the internal wave (wavelength, amplitude, and densities of the fluid layers) and on the average bubble radius. Numerical simulations with different parameters of the internal wave showed that the heterogeneity of the bubble layer parameters (number of bubbles, void fraction, and speed of sound) becomes more evident as the orbital velocities of fluid particles increase. Nevertheless, the solution is qualitatively the same as in Figs. 2–5.

V. INTERNAL WAVE AS THE MAIN CAUSE OF SURFACE WAVE BREAKING

In this section, we consider the case where the breaking of the surface waves is primarily caused by their modulation with a horizontal current, due to an internal wave propagating along a shallow pycnocline. This situation is typical for weak winds when the wind speed is less than 5 m/s. We assume that the internal and surface waves are copropagating. In this case, we need to find the spatially inhomogeneous source term for the injected bubbles \( q(x,z,t) \) by relating the surface wave breaking to the internal wave field. Here we adapt an approach used in a study of the role of tidally forced flow-topography interaction in the aeration of the subsurface waters.21

We are concerned with surface waves riding on a long internal wave \( u_i = u_i(x - c_i t, z) \), slowly varying relative to the surface wave. There exists an extensive literature on the modulation of surface waves by a background current, beginning with Refs. 35–38. These theories can be adapted to the modulation of surface waves by an internal wave, where it is assumed that the background current is that determined by the horizontal velocity field at the free surface due to the underlying internal wave (see, for instance, Refs. 39 and 40).

An alternative model commonly used for the interpretation of images of the surface signature of internal waves was introduced in Ref. 41; here the surface wave field is maintained by a strong wind and the internal wave is regarded as a perturbation to this field. A summary of these studies is given in Appendix B.

Here we assume the absence of the strong wind. Then, in the reference frame which moves with the speed of the internal wave, the internal wave current becomes \( V(X) = u_i(X,0) - c_i \), where \( X = x - c_i t \) and the amplitude of the modulated deep-water surface wave is given by

\[
\frac{a_i^2(X)}{a_i^2_0} = \frac{2}{\sqrt{\frac{V(X)}{c_0} + 1}} + \frac{1}{4} \left[ \frac{V(X)}{c_0} + 1 \right]^{1/2} \left[ \frac{V(X)}{c_0} + 1 \right]^{1/2} - 2,
\]

where \( a_i^2 = (g/c_0)^{1/2} \).

For positive and increasing, the surface wave energy \( a_i^2 \) decreases, while for \( V \) negative and decreasing, \( a_i^2 \) increases to infinity at the stopping velocity \(-c_0/4\). In this case, wave breaking will occur before the stopping velocity. Note that we can use the formulae in Appendix A to relate \( V(X) = u_i(X,0) - c_i \) to the internal wave amplitude at the pycnocline. In particular, the surface current is opposite in sign to the phase speed over the wave crest and in sympathy over the wave trough, with the maximum downwelling region in between. Thus the surface waves steepen as they approach the internal wave crest, and diminish as they approach the wave trough.

Expression (11) predicts that when the surface waves propagate into an opposing current of increasing strength \( V < 0, V_X < 0 \), then the surface wave amplitude grows indefinitely up to the stopping velocity. In practice, the surface waves will break at locations \( X_c \) determined by the criterion

\[
\kappa a_s = (\kappa a_s)_c = S_c,
\]

where \( S_c \) is the critical steepness, after which the waves break. In Ref. 21, it was suggested that \( S_c \) can vary in practice over the range 0.15–0.5 and we note that the theoretical critical value for the wave of maximum steepness is \( S_c = 0.44 \) (see Ref. 42, for instance). Combining the criterion (13) with Eqs. (11) and (12), we get that
\[
\frac{\kappa_a^2 a_0^2}{\kappa_0^2} = \frac{1}{2} \left[ \frac{V(X)}{c_0} + \frac{1}{4} \right]^{-1/2} \left\{ \frac{1}{2} + \left[ \frac{V(X)}{c_0} + \frac{1}{4} \right]^{-1/2} \right\}^{-6}, \quad \frac{\kappa_0 a_0^2}{\kappa_0^2} = \frac{S_c}{S_c^2},
\]

(14)

where we recall that the subscript 0 indicates values at the location where \( V = 0 \). It is readily shown from Eq. (14) that \( \kappa_a \) increases as \( V(X) < 0 \) decreases. This expression is now applied to the internal wave with \( V(X) = u_i(X_0, 0) - c_i \), where the internal wave horizontal velocity field \( u_i \) is found from expression (A7) in the upper layer and whose interfacial displacement field is given by Eq. (A6). These expressions then define a possible breaking zone which lies over the crest of the internal wave, since this is where \( V(X) \) reaches its minimum negative value. Let \( X_m = 2\pi/k \) denote the location of one internal wave crest, where \( k \) is the internal wave number. Then the possible breaking zone is defined by \( X_{c1} < X < X_{c2} \), where \( X_{c1} < X_m \) and since the internal wave (A6) is symmetric about the crest, \( X_{c2} = 2X_m - X_{c1} \). For a periodic internal wave, this breaking zone is then repeated periodically, around each internal wave crest.

In this zone, we need to determine the energy released by wave breaking and available for the injection of bubbles. The wave energy at any location \( X \) in the absence of breaking is \( E = \rho_g a_0^2/2 \), where \( a_0(X) \) is given by Eq. (11). Next we follow Ref. 21 and assume that the wave energy of a breaking wave is \( \rho_g a_0^2/2 \), where the breaking wave amplitude is defined by the condition that \( a_0, \kappa = S_c \) throughout the breaking zone and the wave number \( \kappa \) is defined by Eq. (12), the same value as in the absence of breaking. Hence the energy available to inject bubbles is the difference between these, given by

\[
\bar{E}_1(X) = E_0 \left\{ \frac{a_0^2(X)}{a_0^2} - \frac{S_c^2}{a_0^2} \kappa_0^2 \right\}, \quad E_0 = \frac{1}{2} \rho_g a_0^2,
\]

(15)

Here \( X \) is constrained to lie in the breaking zone. We then further assume that a fraction \( E_{br} = \varepsilon \bar{E}_1 \) of this breaking wave energy is available for the injection of bubbles and, following Ref. 21, we set \( \varepsilon = 0.003 \), appropriate for spilling breakers.

On the other hand, the energy per unit volume needed to submerge a single bubble of radius \( a \) to a depth \( z \) is given by

\[
E_b = -\frac{4}{3} \pi a^3 \rho_g z.
\]

Then, from an energy balance, we get that

\[
E_{br} = \varepsilon \bar{E}_1 = -\int_{-H}^{0} \frac{4}{3} \pi a^3 \rho_g z \bar{N} \,dz,
\]

(16)

where \( \bar{N} \) is the number of newly born bubbles per unit surface area, given by

\[
\bar{N} = \beta_0(X) \exp \left( \frac{z}{\gamma} \right),
\]

with \( \gamma = a_0(X)/4 \) (see Ref. 21), where \( \beta_0(X) \) can be found from Eq. (16). If we make a simplifying assumption that all newly born bubbles have the same initial radius \( a_0 = 50 \mu m \) (equal to the bubble radius at \( z = 0 \), when the fluid is in rest), then we can integrate Eq. (16) explicitly, assuming that \( H/\gamma \gg 1 \),

\[
E_{br} = \frac{4}{3} \pi \rho_g \beta_0(X) \gamma a_0^3,
\]

and thus

\[
\bar{N}(X, z) = \frac{3}{4\pi \rho_g \gamma a_0^3} \exp \left( \frac{z}{\gamma} \right)
\]

(17)

is the number density of newly injected bubbles over the breaking zone. These bubbles are injected over every period \( P_s = 2\pi/\Omega_0 \) of the surface wave and so finally we get an upper estimate for the source term in the possible breaking zone,

\[
q_{max}(X, z) = \frac{\bar{N}(X, z)}{P_s},
\]

(18)

while it is zero outside this zone. Expression (18) assumes that the breaking surface waves can be represented as a steady-state field over the breaking zone. In that representation, the entire surface wave field (B4) is replaced by breaking waves. However, assuming that the breaking is due to spilling breakers, in practice only a small region around each surface wave crest will create breaking wave energy available for the creation of bubbles. In this scenario, at each particular fixed location \( X \) in the breaking zone, we use a local representation of the surface wave defined by Eq. (B4), namely,

\[
\zeta_s = a_0(X) \cos[\kappa(X)X - \Omega_0(T - T_0)],
\]

(19)

where \( T_0 \) is a phase constant. Recall that in this breaking zone \( \kappa(X)a_0(X) \approx S_c \) and so, for each fixed \( X \), the local steepness \( \kappa(X) \zeta_s \approx S_c \) over some small time interval \( T_1 < T < T_2 \), where surface wave breaking occurs. Without loss of generality, we can suppose that \( T - T_0 \approx (\kappa(X)a_0(X) - 3\pi/2)/\Omega_0 \). Then let \( T_1 \) denote that moment of time when the local breaking condition

\[
\kappa(X) \zeta_s(X, T) = \kappa(X) a_0(X) \cos[\kappa(X)X - \Omega_0(T - T_0)] = S_c
\]

(20)

is first satisfied at this fixed point \( X \), that is, the equality that holds in Eq. (20). Then as \( T \) increases, we let \( T_M \) denote that moment of time when \( \zeta_s(X, T) \) reaches its maximum value for the first time. Although technically the breaking condition (20) continues to hold until \( T_2 = 2T_M - T_1 \), we note that for \( T_M < T < 2T_M - T_1 \), the rate of energy loss is negative and no bubbles will be injected. Then \( \Delta T_b = T_M - T_1 \) is the duration of a breaking event at \( X \), which is then repeated periodically with a period \( P_s = 2\pi/\Omega_0 \).

The next task is to find the energy \( \bar{E}_2 \) generated by this breaking wave which is available for the injection of
bubbles. To this end, we assume that over the time interval $\Delta T_p$, the crest of the local expression (19) for a nonbreaking wave is replaced by a “flat cap” of constant amplitude $\tilde{a}_s$, determined by the breaking condition that $\kappa \tilde{a}_s = \tilde{S}_c$ [compare the analogous discussion above leading expression (15)]. Then the wave potential energy lost in this breaking zone is available for the injection of bubbles. In the absence of breaking, the potential energy is $\rho g \xi_c^2/2$ where $\xi_c$ is given by Eq. (19) and is time-dependent. As above, the potential energy of the breaking wave is $\rho g \tilde{a}_s^2/2$. Hence the available energy is

$$E_2(X,T) = E_0 \left\{ \frac{\tilde{a}_s^2}{a_{\phi 0}^2} \cos^2 \kappa(X) X - \Omega_0[T - T_0] \right\}$$

$$- \frac{\kappa^2}{\kappa_0^2} \tilde{S}_c^2 \xi_c^2$$

This expression holds only in the possible breaking zone over the time interval $\Delta T_p$, where the inequality (20) holds; $E_0$ is defined above in Eq. (15), while the terms $\kappa^2/\kappa_0^2$ and $\kappa^2/\kappa_0^2$ are defined by Eqs. (B11) and (B9), respectively. The remaining calculation now proceeds as above for the steady-state case, where we replace $E_1$ with $E_2$ in each of the expressions leading to Eq. (17). The essential difference is that now the rate of injection of bubbles occurs over the interval $\Delta T$, and is repeated over many surface wave periods $P_s = 2 \pi/\Omega_0$. Then we define the time-dependent upper estimate for the source term by

$$q_{\text{max}}(X,z,T) = \frac{\partial \bar{N}(X,z,T)}{\partial T}$$

for $T_1 + k P_s < T < T_M + k P_s, \quad k = 0, 1, 2, \cdots$, or $q_{\text{max}}(X,z,T) = 0$ otherwise, (21)

where

$$\bar{N}(X,z,T) = \frac{3}{4 \pi} \frac{\tilde{E}_2(X,T)}{\rho g \gamma^2} \exp \left( -\frac{z}{\gamma} \right).$$

As before, this expression holds only when $X$ lies in the spatial possible breaking zone defined by Eq. (14) (repeated near every internal wave crest). Note that indeed $q(X,z,T) \geq 0$ as required for bubble injection. It can be shown that averaging expression (21) over the phase $T_0$ recovers the steady formula (18).

For our numerical results, we show only those using the time-dependent source term (21). Averaged results are similar to those obtained using the steady-state form (18). To account for the attenuation of the breaking surface wave, as well as for possible deviation toward predictions of the theory in Ref. 41 (see discussion at the end of Appendix B), we use a simple phenomenological model, where we replace the upper estimate obtained above by the expression

$$q(X,z,T) = q_{\text{max}}(X,z,T)e^{-(X-X_{c1})/\delta},$$

for $X_{c1} \leq X \leq X_{c2}$ and similarly for other possible breaking zones. Here, the choice $1/\delta \rightarrow 0$ recovers the upper estimate for $q$. We then can choose the value of this constant $\delta$, which represents the effective width of the breaking zone. In the following, we compare the results obtained for the upper estimate (21) and for the attenuated expression (22), where the constant $\delta = X_M - X_{c1}$, i.e., breaking effectively takes place in the area $X_{c1} < X < X_M$. (We assume that the value of this constant can be potentially obtained more accurately from experimental and observational results.)

Figure 6 shows the distribution of void fraction for the wind speed $W = 2.5$ m/s, when bubbles are injected by breaking surface waves due to interaction with a copropagating internal wave. We compare the distributions obtained for the source term given by the expressions (21) [shown in Fig. 6(a)] and (22) [shown in Fig. 6(b)]. Figure 6 also shows the average value of the source term $\bar{q}$ for these two expressions, where

$$\bar{q}(X) = \frac{1}{5 P_s} \int_{5 P_s}^{10 P_s} \int_{-T}^{0} q(X,z,T) dz dT.$$

Figure 7 shows the acoustic speed corresponding to the distribution in Fig. 6(b) [also reproduced in Fig. 7(b)]. To model the surface waves we used the following parameters: $S_e = 1/2$, $a_0 = 0.1$ m, $\lambda_0 = 5$ m, $\kappa_0 a_0 = 0.25 < S_e$, and $\gamma = 0.25 a_0$. According to our results, the region of injection of bubbles is again situated in the downwelling area behind the crest of the internal wave, as we found for the homogeneous input of bubbles from the surface for strong winds (see Fig. 2 for comparison). But in this case the inhomogeneity of the distribution of bubbles in the subsurface layer is much stronger, since bubbles are injected only through parts of the surface.

Figure 8 shows the averaged distribution of void fraction $\bar{\alpha}$ with depth for three different models of injection of bubbles, a homogeneous case ($W = 10$ m/s), and two inhomogeneous cases ($W = 2.5$ m/s, and we use either Eq. (21) or Eq. (22) for the source). Here

$$\bar{\alpha}(z) = \frac{1}{5 P_s} \int_{5 P_s}^{10 P_s} \int_{0}^{X} \alpha(x,z) dx dT.$$

We note that the averaged values of $\bar{q}$ and $\bar{\alpha}$ are close to the respective solutions corresponding to the steady source (18). The inhomogeneous input of bubbles leads to the more rapid decrease of the void fraction with depth, despite larger average value at the surface.

The detailed character of the bubble distribution in the subsurface layer depends on the parameters governing the breaking surface waves, that is, the initial wave number $\kappa_0$, the initial amplitude $a_0$, and the critical steepness $S_e$. The spatial distribution of $N$ for different values of wavelength and $S_e$ are shown in Figs. 9 and 10. In Fig. 9, the number density of bubbles is shown for $a_0 = 0.1$ m and three different values of $\lambda_0 = 2, 2.5, \text{and} 2.3$ m $(\kappa_0 a_0 = 0.24, 0.25 \text{and} 0.27, \text{respectively})$.
\( \lambda_0 = 2.3 \) m, surface waves begin to break at low horizontal velocities and the picture is closer to the case of homogeneous input of bubbles (e.g., Fig. 2) than in the remaining two cases. For \( \lambda_0 = 2.6 \) m, breaking of surface waves occurs in the narrow zones on the surface.

In Fig. 10, the same pictures are plotted for different \( S_c \). We chose \( S_c = 0.5 \) (basic value), 0.45, and 0.4 (in this last case the initial steepness already exceeds the critical value). Here, \( \lambda_0 = 2.5 \) m and \( a_0 = 0.1 \) m. As can be seen from the plots, the smaller is \( S_c \) the wider is the region of surface waves breaking. Nevertheless, at a depth of 3 m and deeper, the character of the distribution of \( N \) does not change noticeably because in this region, it is mainly defined by the slow convection.

The considerations above can be also applied to the case when the surface waves and the internal wave move in the opposite directions, with the appropriate changes for \( V(X_0) \) and \( \Omega_0 \). However, \( V(X_0) \) will always be positive for the case

**FIG. 6.** (Color online) Void fraction of bubbles and averaged value of source term for periodic internal wave of 3 m amplitude and wind speed \( W = 2.5 \) m/s (structure due to inhomogeneous breaking). The source term is calculated (a) using Eq. (21) and (b) using Eq. (22).

**FIG. 7.** (Color online) (a) Acoustic speed (meters per second) and (b) void fraction of bubbles (1/m³) for periodic internal wave of 3 m amplitude and wind speed \( W = 2.5 \) m/s (structure due to inhomogeneous breaking).
of counterpropagating internal and surface waves and hence we expect surface wave breaking to be not so prominent.

VI. CONCLUDING REMARKS

In this paper we have modeled the shaping of the subsurface bubble layer by an internal wave. The effect of an internal wave on the surface wave breaking and, thus, on the subsurface bubble layer, was first observed in Ref. 18. Recently, structure formation in the bubble layer in accordance with the profile of the underlying internal wave was recorded on the shelf of Sea of Japan in Refs. 19 and 20.

We considered an uncoupled problem formulation using the solution for an internal wave in a two-layer fluid, which was then substituted into the equation describing the bubble dynamics. We studied two different cases, when breaking is caused either by a strong wind or by the interaction with an internal wave. We have proposed a simple analytical model for the injection of bubbles through the surface due to the modulation and breaking of surface waves induced by an internal wave. The equations were solved numerically, showing structure formation in the bubble layer.

The mathematical model used in our study for the very complex processes in the turbulent ocean is highly idealized. In particular, in the case when breaking is caused by a strong sustained wind, it is desirable to try to develop this study further to account for the effects of Langmuir circulation, which also plays a significant role in the dynamics of bubbles (see Refs. 32–34). In the case when surface waves breaking is caused by a direct interaction with an internal wave, it is interesting to consider an oblique interaction. For simplicity, in the current study we used a solution for a linear sinusoidal internal wave. However, large amplitude nonlinear internal waves are commonly observed in the coastal oceans (e.g., Ref. 23 and references therein) and one could consider the organization of bubbles by such nonlinear waves. The theoretical framework developed in this paper can be generalized to account for these extensions.

The described effects are twofold: bubbles are driven by an internal wave field and the injection of bubbles into the water is enhanced due to the steepening of surface waves by the internal wave. We have shown that both of these mechanisms increase the void concentration of bubbles in the downwelling areas behind the crests of the internal wave, which agree with the observations in Refs. 18–20.

We also calculated the characteristics such as bubble void fraction, acoustic wave speed in the mixture, and scattering intensity, and showed that the structure formation in the bubble layer can have a strong effect on the acoustics in the subsurface layer. We have shown that the horizontal variability of these characteristics approximately copies the internal wave, with a shift in the direction of the propagation of the internal wave. The magnitude of such variability is depth-dependent.

Thus, processes of this type should be important for the study of underwater acoustics and the related oceanographic measurement techniques based on acoustic Doppler current profilers (ADCPs).

APPENDIX A: INTERNAL WAVES IN A TWO-LAYER FLUID

In this appendix, we present a brief summary of the well-known solution for a linear internal wave, summarizing all necessary formulae (e.g., Refs. 26–28). We suppose that the flow is two-dimensional and use the spatial coordinates \((x,z)\), where \(x\) is horizontal and \(z\) is vertical. The undisturbed free surface is at \(z=0\). The upper layer has an undisturbed constant depth \(h\) and a constant density \(\rho_1\), while the lower layer has an undisturbed constant depth \(H-h\) and a constant density \(\rho_2\) (\(H\) is the total depth). We consider an inviscid, incompressible fluid.

Let \(u_i, w_i\) denote the horizontal and vertical components of the velocity field, \(p_i\) be the pressure deviation from the hydrostatic pressure, and \(\rho_i\) be the density in each layer (1 and 2 denote the upper and lower layers, respectively). The linear internal wave field is then easily found by solving the linearized Euler equations in each layer

\[
\rho_i u_i + p_i = 0, \quad \rho_i w_i + p_i + \rho_i g = 0, \quad u_{ix} + w_{iz} = 0,
\]

subject to the usual rigid lid condition at the surface

\[
w_{1z}\big|_{z=0} = 0, \quad \text{(A1)}
\]

rigid bottom condition at \(z=-H\)

\[
w_{2z}\big|_{z=-H} = 0, \quad \text{(A2)}
\]

and linearized continuity conditions for the vertical velocity and pressure at the interface

\[
w_1\big|_{z=-h} = w_2\big|_{z=-h} = 0, \quad \text{(A3)}
\]

\[
p_1 - p_2\big|_{z=-h} = -(p_2 - p_1)g\zeta, \quad \text{(A4)}
\]

where \(\zeta\) denotes the elevation of the interface from the undisturbed level \(z=-h\). Assuming that \(p_2 - p_1 \ll p_1, p_2\), and denoting \(\Delta p = (p_2 - p_1)/p_2\), Eq. (A4) yields an interface condition in the form

\[
w_{1x}\big|_{z=-h} - w_{2x}\big|_{z=-h} = -\Delta p g \zeta_{xx}, \quad \text{(A5)}
\]

Then the solution is found by solving the Laplace equation in each layer

\[
w_{ixx} + w_{icz} = 0, \quad i = 1, 2,
\]

subject to the conditions (A1)–(A3) and (A5).

Next, let

\[
\zeta(x,t) = A e^{i(kx-\omega t)} + c.c., \quad \text{(A6)}
\]

and then we find that the internal wave field in the upper layer is given by

\[
u_1 = -\frac{i\omega A}{\sinh kh} \cosh kze^{i(kx-\omega t)} + c.c., \quad \text{(A7)}
\]

\[
w_1 = \frac{i\omega A}{\sinh kh} \sinh kze^{i(kx-\omega t)} + c.c., \quad \text{(A8)}
\]

\[
p_1 = -\frac{\omega^2 A}{k \sinh kh} \cosh kze^{i(kx-\omega t)} + c.c.,
\]

The total pressure in the upper layer is

\[
p_{1\text{total}} = p_a - \rho_1 g z + p_1, \quad \text{(A9)}
\]

where \(p_a\) is the atmospheric pressure. The linearized internal wave field in the lower layer is given by

\[
u_2 = \frac{i\omega A}{\sinh kh} \sinh k(z + H)e^{i(kx-\omega t)} + c.c., \quad \text{(A10)}
\]

\[
w_2 = -\frac{i\omega A}{\sinh kh} \cosh k(z + H)e^{i(kx-\omega t)} + c.c., \quad \text{(A11)}
\]

\[
p_2 = \frac{\omega^2 A}{k \sinh kh} \cosh k(z + H)e^{i(kx-\omega t)} + c.c. \quad \text{(A12)}
\]

The dispersion relation is given as follows:

\[
\omega^2 = \Delta p g k \tanh kh \cdot \tanh k(H-h) + \tanh kh.
\]
APPENDIX B: MODULATION OF SURFACE WAVES BY AN INTERNAL WAVE

The modulation of surface waves by a background current was studied in Refs. 35–38. These theories were adapted to the modulation of surface waves by an internal wave (see, for instance, Refs. 39 and 40). An alternative model commonly used for the interpretation of images of the surface signature of internal waves was introduced in Ref. 41 under the assumptions that the surface wave field is maintained by a strong wind and the internal wave is regarded as a perturbation to this field. Here we present a brief summary of these theories and present the main results needed for our present study. In particular, we will emphasize the distinction between a fixed reference frame (that used by an observer at a fixed place) and the reference frame, which moves with the internal wave and in which the internal wave is steady.

First, consider the Euler equations in the fixed reference frame. Using \(x,z,t\) coordinates, the horizontal momentum equation is

\[
    u_t + uu_x + wu_z + p_x = 0. \tag{B1}
\]

We are concerned with surface waves, with a horizontal velocity field \(u_x\), riding on the surface current of an internal wave \(u_i = u_i(x - c_i t, z)\). Linearization then yields

\[
    u = u_i + u_s, \quad u_{it} + u_i u_{ix} + [u_i u_{ix} + w_i u_{iz} + w_s u_{iz}] + p_{xz} = 0. \tag{B2}
\]

On the assumption that the internal wave is a long wave and slowly varying relative to the surface wave, the terms \([\cdots]\) can be neglected at the leading order, but this is not essential at the moment.

Then to facilitate the analysis, we make a change of variables

\[
    X = x - c_i t, \quad T = t, \quad Z = z, \quad U = u, \quad W = w, \quad P = p,
\]

so that Eq. (B1) becomes

\[
    u_T + (u - c_i)u_X + wu_Z + p_X = 0
\]

and Eq. (B2) becomes

\[
    u_{iT} + (u - c_i)u_{iX} + [u_i u_{ix} + w_i u_{iz} + w_s u_{iz}] + p_{iZ} = 0. \tag{B3}
\]

In effect, the internal wave current \(u_i(x - c_i t, z)\) becomes \(u_i(X,Z) - c_i\). Alternatively, we can make a change of variables, preserving Galilean invariance

\[
    X = x - c_i t, \quad T = t, \quad Z = z, \quad U = u - c_i, \quad W = w, \quad P = p,
\]

so that

\[
    U_T + UU_X + WU_Z + P_X = 0.
\]

But now, the linearization is about \(U_i(X,Z) = u_i(X,Z) - c_i\), that is \(U = U_i + u_s\), and so again we get Eq. (B3). That is, both transformations lead to the same equation for the calculation of the modulated surface wave field.

Now we can apply a WKBJ-type analysis to the modulation of surface waves by slowly varying current (see, for instance, Refs. 38, 40, 43, and 44). The outcome is that the dispersion relation is the same as when the internal wave is omitted, except for the Doppler shift by the surface current \(V(X) = u_i(X,0) - c_i\), and then the equation for conservation of waves determines how the surface wave number will be modulated. The surface wave amplitude is governed by the wave action equation. The fact that only \(u_i(X,0)\) is needed requires some careful work, but is essentially the outcome of the long-wave hypothesis for the internal wave and the assumption that the internal wave is slowly varying relative to the surface wave. Thus, in the comoving frame, a modulated deep-water surface wave of elevation \(\zeta_s\) is described by

\[
    \zeta_s = a_s \cos \phi, \quad \phi_T = -\Omega, \quad \phi_X = \kappa, \tag{B4}
\]

where the frequency \(\Omega\), wave number \(\kappa\), and amplitude \(a_s\) are slowly varying functions of \(X,T\) determined by the equations

\[
    \Omega = V(X)\kappa + \kappa^*, \quad \Omega^* = g|\kappa|, \tag{B5}
\]

\[
    \kappa_T + \Omega_X = 0, \tag{B6}
\]

\[
    A_T + (c_3 A) \chi = 0, \quad A = \frac{E}{\Omega^*}, \quad E = \frac{1}{2} \rho g a_s^2, \quad c_s = \frac{\partial \Omega}{\partial \kappa}, \tag{B7}
\]

Here, \(A\) is the wave action density and \(E\) is the wave energy density. These equations have the steady solution in which \(\kappa\) is a constant and \(\kappa, a_s\) depend only on \(X\)

\[
    \Omega = \Omega_0, \quad \phi = \int_{X_0}^{X} \kappa(X')dX' - \Omega_0 T, \quad \frac{\rho c_g^4 a_s^2}{2\Omega^*} = F_0. \tag{B8}
\]

where \(\Omega_0, F_0\) are constants. The dispersion relation then provides a prescription for the dependence of \(\kappa = \kappa(V)\), which is better expressed in terms of the intrinsic phase speed

\[
    c^* = \frac{c_0 [V(X) + c^*]}{c_0} = 0, \tag{B9}
\]

Here, without loss of generality we have chosen \(\kappa > 0\). The solution for \(c^*, \kappa, c_s\) is

\[
    c^* = \frac{c_0}{2} + \frac{c_0}{4} \left[ \frac{V(X)}{c_0} + \frac{1}{4} \right]^{1/2}, \quad \frac{\kappa}{c^*} = \frac{c_0^2}{c_s^2}, \quad \frac{c_s}{c_0} = \frac{\sqrt{V(X)(1/4)}}{c_0}. \tag{B10}
\]

Now choose \(c_0\) to be \(c^*(V=0)\), so that the plus sign is chosen and again, without loss of generality, we can choose \(c_0^* > 0\), so that the surface waves propagate in the positive \(x\)-direction. For \(V > 0\) the surface waves propagate without restriction and \(c^*\) decreases as \(V\) increases, while for \(V < 0\), \(c^*\) increases to infinity as \(V\) decreases to the stopping velocity of \(-c_0/4\). The wave amplitude is given by Eq. (B8) which reduces to

\[
    \zeta_s = a_s \cos \phi, \quad \phi_T = -\Omega, \quad \phi_X = \kappa, \tag{B4}
\]
For $V$ positive and increasing, the surface wave energy $a^2$ decreases, while for $V$ negative and decreasing, $a^2$ increases to infinity at the stopping velocity. In this case wave breaking will occur before the stopping velocity.

This well-known solution (B11) for the modulation of surface waves by a slowly varying current assumes that the surface wave field is essentially unforced. In the situation when there are strong winds, this assumption needs to be relaxed. Following Ref. 40, we assume that there is a dominant wave number in the wind-wave field, the dispersion relation still holds, and so Eqs. (B5) and (B6) can again be used to yield the expressions (B9) and (B10). But the wave action equation is changed by the presence of source and dissipation terms. Thus, in the comoving frame, the wave action Eq. (B7) is changed to

\[ A_T + c_g A_X = S - D, \quad A = \frac{\rho g a^2}{2 \Omega^*}, \quad c_g = \frac{\partial \Omega}{\partial \kappa}. \]  \hspace{1cm} (B12)

Here $S$ is a source term, and $D$ is a “dissipation” term representing nonlinear interactions and energy loss to small scales (possibly through wave breaking). The solution of this equation now requires a more detailed knowledge of these source and dissipation terms. However, we can follow an approach pioneered in Ref. 41 in which Eq. (B12) is used to determine $A = A(\kappa)$. First assume that there is steady state in which $\kappa = \kappa_0$ (a constant), $A = A_0 = A(\kappa_0)$ so that $S = D$. Then suppose that this steady state is perturbed by the effect of the internal wave surface current $V(X) = \tau_0(X, 0) - c_i$. Then $\kappa = \kappa_0 + \delta \kappa$, $A = A_0(\kappa) + \delta A$ is the action density of the perturbed state, and following Ref. 41, we assume the perturbation of $S - D$ to be $-\mu \delta A$. Here $\mu$ is an empirically determined constant, such that $\mu^{-1}$ is typically of the order 10–100 wave periods. The perturbed wave kinematic Eqs. (B5) and (B6) yield the outcome

\[ \frac{\delta \kappa}{\kappa_0} = -\frac{V(X)}{c_i \kappa_0}, \quad \sin \Omega = V(X) \kappa + \Omega' \kappa = \Omega_0, \]

while the perturbed action spectrum is given by

\[ \delta A_T + c_i \delta A_X + \left( 1 - \frac{\kappa_0 \frac{\partial c_i}{\partial \kappa_0}}{c_g \frac{\partial \kappa_0}{\partial \kappa} - \frac{\partial A_0}{\partial \kappa_0}} \right) A_0 V_X = -\mu \delta A. \]

Here the subscript 0 refers to the steady state without the modulations induced by the internal wave and we note that $\kappa_0 \frac{\partial c_i}{\partial \kappa_0} - c_g \frac{\partial \kappa_0}{\partial \kappa} = -c_i \frac{\partial \kappa_0}{\partial \kappa} \kappa_0 / 2$. Following Ref. 41, we assume that the relaxation term on the right-hand side dominates over the local term $\delta A_T + c_g \delta A_X$, which then yields the quasisteady state solution

\[ \frac{\delta A}{A_0} = -\frac{3 + 2 \beta}{2 \mu} V_X, \quad \beta = -\frac{\kappa_0 \frac{\partial A_0}{\partial \kappa_0}}{A_0 \frac{\partial \kappa_0}{\partial \kappa_0}}, \]  \hspace{1cm} (B13)

which is similar to the formula obtained in Ref. 41. For a spectrum $E \sim \kappa^{-4}$, or $A \sim \kappa^{-9/2}$, $\beta = 9/2$, and 3/2 + $\beta = 6$.

Next we note that the corresponding action change due to the modulation of the surface wave directly by the internal wave current $V(X)$ in the absence of any wind is expressed by Eqs. (B7) and (B8), which for small values of $V(X)$ yields to leading order

\[ \frac{\delta A}{A_0} = -\frac{3 V(X) \kappa_0}{\Omega_0}. \]  \hspace{1cm} (B14)

Note that expression (B13) peaks at the downwelling center, while expression (B14) peaks over the crest of the internal wave, in the absence of any wave breaking. For the interfacial wave described in Appendix A, the ratio of these terms can be estimated in magnitude as $(3 + 2 \beta / \kappa_0 / \kappa_0 / 2 \mu)$, where $k$ is the wave number of the interfacial wave. In the oceanic situation, $k \ll \kappa_0$ but $\Omega_0 \approx 2 \pi \mu$, and so which term dominates depends on the actual case being considered. A typical scenario might have $k / \kappa_0 \approx 10^{-2}$, while $\Omega_0 / 2 \pi \mu$ varies in the range 10–100; then the ratio varies in the range 1–10 in order of magnitude, suggesting that usually it will be the first term which dominates. However, we must recall that expression (B13) is derived on the assumption that the internal wave field is quite weak ($V \ll c_0$) and for stronger internal wave fields, we would expect expression (B11) derived for unforced surface wave fields to hold.
