A high yielding rearrangement of epoxy-esters, under Lewis acid conditions, to give bicyclic ortho esters is reported.

We have an interest in the development of new methods to prepare heterocyclic systems; including stoichiometric organometallics,1 palladium mediated reactions,2 biomimetic methods,3 condensation of reactive electrophilic systems.4 We now wish to report a new route to methoxy substituted dioxabicyclo[3.2.1]octane systems using a epoxy-ester to ortho ester rearrangement.

The rearrangement of epoxy-esters to ortho esters is a well established reaction.5 It has found applications in the protection of carboxylic acids,6 in total synthesis of natural products,7 and also in numerous elegant biomimetic chemistry.8 The majority of the reports focused on the formation of a trioxabicyclic ortho ester where the epoxide of the precursor is in the alkoxide part of the ester (Type I, Scheme 1). Our curiosity led us to investigate the formation of a lesser-known configuration of bicyclic ortho ester starting from a precursor where the epoxide is linked to the carbonyl of the ester (Type II, Scheme 1).

Scheme 1 Epoxy-ester to ortho ester rearrangement.

To our knowledge there have been only two reports of this type of reaction, both being in the field of diterpene chemistry (Scheme 2).9,10 Urones has reported the unexpected formation of such an ortho ester during a Sharpless asymmetric epoxidation of a diterpene.9 The chemistry was further used in the semisynthesis of bioactive drimanes, pereniporin B and warburganal, but no follow up on the ortho ester chemistry.10 We believe this reaction warrants further exploration since ortho ester remain an under exploited functional group in organic chemistry, thus giving access to unusual compounds and opens up the development of new chemical space. Herein we report our preliminary studies.
This successful initial result was followed up by possible optimisation under a range of reaction conditions (Table 1). The same substrate (2) was reacted using a limited range of Lewis Acids, solvents and conditions. The most successful Lewis acids were found to be ZnBr₂ and Yb(OTf)₃. Some variations in the diastereoselectivity was seen with ZnBr₂ depending on the reaction conditions while Yb(OTf)₃ giving essentially one diastereoisomer. The chlorinated solvents DCM and DCE appear to be best solvents for this reaction and it typically ran smoothly at room temperature over a period 8 hours.

Table 1 Results of Lewis acids used and reaction conditions.

The next extension to the work was to explore the possibility of introducing a substituent on the epoxide. To this end gem-dibstituted epoxides (9-10) were prepared in order to examine the additional alkyl group’s influence on cyclisation under Lewis acid conditions. It was gratifying to find that both examples worked well giving products (11-12) combined yields of 77% and 90% respectively, in a rough ration of 1:2, showing a substituent at this position has little impact on the reaction (Scheme 6).

Following the above positive results, we turned our attention to 1,2-disubstituted epoxides (13) and (14) analogous to investigation by Sum and Weiler into the stereochemical outcome of the Lewis acid catalysed isomerisation of epoxides to give ketal. They have shown the epoxide ring opening was stereospecific by using cis and trans epoxides. We therefore undertook similar work to see if the rearrangement of epoxy-ester to ortho ester reaction was also stereospecific. The epoxides (13) and (14) were readily prepared by alkylation, subsequent epoxidation from respective Z and E alkenes (Scheme 7).

The results are inline with the findings of Sum and Weiler that the reaction occurs with nucleophilic ring opening of the epoxide by the oxygen lone pair leading to inversion of stereochemistry at that centre to give ortho ester (15a-b) and (16a-b). The mechanism and stereoselectivity of the reaction can be rationalised as below (Scheme 8). The variation in diastereoselectivity with the Lewis acid (Table 1) and the evidenced of inversion of epoxide (Scheme 7) suggest to us there is some coordination, or pre-organisation, between the epoxide and non-reacting ester before ring opening of the epoxide. Simple models suggest that a 7-membered chelate would still allow for backside attack on the epoxide by the non-chelated ester. Further experimental work and modelling on this aspect is ongoing.
The electron donating effect of the alkoxy group. However, it may be since the ester group is marginally more nucleophilic due to no change is observed. The result was somewhat unexpected.

19a the malonic ester center during the reaction that could be proved chemistry also is an interesting example of desymmetrisation of a useful addition to the field of ortho esters synthesis. The result was somewhat unexpected.

the case that the Lewis acid is coordinating strongly to the ester group thus reducing its nucleophilicity.

Conclusions

We have thus established a high yielding versatile route to methoxy substituted dioxabicyclo[3.2.1]octanes, we believe this is a useful addition to the field of ortho esters synthesis. The chemistry also is an interesting example of desymmetrisation of the malonic ester center during the reaction that could be proved useful. We are currently looking at expanding the reaction, by controlling the stereochemistry, cascade reactions and applications in synthesis.
