Abstract

The aim of the current investigation was to explore the lateral stiffness of different sports wheelchair wheels available to athletes in a ‘new’ and ‘used’ condition and to determine the effect of (a) stiffness, (b) tyre type (clincher vs. tubular) and (c) tyre orientation on the physiological and biomechanical responses to submaximal and maximal effort propulsion specific to wheelchair basketball. 8 able-bodied individuals participated in the laboratory-based testing, which took place on a wheelchair ergometer at two fixed speeds (1.1 & 2.2 m·s⁻¹). Outcome measures were power output and physiological demand (oxygen uptake & heart rate). 3 participants with experience of over-ground sports wheelchair propulsion also performed 2 x 20 m sprints in each wheel configuration. Results revealed that wheels differed significantly in lateral stiffness with the ‘new’ Spinergy wheel shown to be the stiffest (678.2 ± 102.1 N·mm⁻¹). However the effects of stiffness on physiological demand were minimal compared to tyre type whereby tubular tyres significantly reduced the rolling resistance and power output in relation to clincher tyres. Therefore tyre type (and subsequently inflation pressure) remains the most important aspect of wheel specification for athletes to consider and monitor when configuring a sports wheelchair.

Keywords: wheelchair configuration; mobility performance, wheelchair propulsion
Introduction

It has been well documented over recent years how wheelchair configuration can affect performance in wheelchair sports, such as wheelchair basketball [1]. Research has typically focused on how major areas of configuration such as the size [2,3] and camber angle [4-6] of the main wheels influence athletes mobility performance. However, there are numerous other features of a sports wheel that may also affect the ergonomics of sports wheelchair propulsion. Wheels currently available to athletes differ in the number, thickness, material and orientation of the spokes, which according to the cycling literature can affect the stiffness of a wheel [7-9].

Wheel stiffness refers to a wheels resistance to deflection under loading [7]. From the cycling literature, Minguez and Vogwell [9] revealed that a reduction in the number of spokes (from 18 to 12) reduces the radial stiffness of wheels. Alternatively, Gavin [8] suggested that increasing the thickness of the spokes (1.6 to 2.0 mm) increases the radial and lateral stiffness of wheels. The material of wheel spokes also differ with steel thought to provide a stronger, fatigue-resistant spoke compared to aluminium or titanium [7]. However, the introduction of composite fibre materials offers a lighter, more expensive alternative [7]. Finally, the orientation of the spokes is also thought to impact wheel stiffness [8]. Wheels can be distinguished by the number of times one spoke is crossed by others (typically 0x [radially spoked], 2x, 3x or 4x) with a greater number of crossings thought to reduce wheel stiffness [8]. Although the majority of the cycling literature has focused on the radial stiffness of the wheel, a key difference in sports wheelchairs is the 15-24° camber angle of the main wheels [5]. Therefore a large percentage of the load placed on the wheel is not radial, suggesting that lateral stiffness would be a more appropriate measure for a sports wheelchair wheel.

Few studies have investigated different spoke configurations specific to wheelchair users [10,11]. Comparisons have been made between Spinergy wheels, which incorporate composite fibre spokes, in relation to conventional steel-spoked wheels [10,11]. However no improvement in physiological demand [10] or reduction in vibrations [11] was identified in Spinergy wheels, despite the perceived improvement in ride comfort [10]. Although no performance benefits were observed, details on the specific differences in wheel specifications, aside from spoke material, were not provided. In order to optimise performance through wheel specification, details of individual components need to be examined to establish reliable cause and effect relationships. It is also worth noting that both
these studies were conducted from a daily-life perspective and as such translations to an
ataltic population are not possible. Another important consideration for the wheelchair user
is wheelchair maintenance, since a poorly maintained wheelchair can increase the physical
strain placed on the user [12]. Therefore it would also be of interest to quantify the impact
that a reduction in spoke tension, which occurs over time in a used wheel, could have on
wheel stiffness and subsequently performance.

In addition to wheel stiffness, wheels currently available to athletes also differ in tyre
type and subsequent inflation pressure. Such parameters have again been investigated under
conditions specific to daily-life wheelchair propulsion and have demonstrated that pneumatic
tyres reduced the physiological demand compared to solid tyres [13,14]. These studies also
revealed that power requirements and physiological demand both increase when tyre pressure
drops to 25% [14] and 50% [13,15] of the recommended inflation pressure. Pneumatic tyres
are the popular choice for athletes participating in wheelchair basketball, however the tyres
themselves can differ in their construction. Clincher tyres are most common, whereby the
tyre extends from both walls of the wheel rim to partially encompass an inner tube [7].
However, an increasing number of athletes are selecting tubular tyres, which do not require
an inner tube as the tyre is completely enclosed and sits within the walls of the wheel rim [7].
Tubular tyres enable a higher inflation pressure and are thought to be less prone to punctures
[7].

As mentioned previously, the main wheels of a sports wheelchair are cambered,
which can deform the tyre and increase resistance [5]. Recently manufacturers such as
Celeritas 300 (Den Haag, Netherlands) have introduced novel developments to the wheel rim
in an attempt to optimally orientate the tyre so that deformation and resistance are minimised.
Yet to the authors knowledge, the impact of tyre orientation on aspects of mobility
performance have not be investigated.

The aims of the current investigation were to: 1) explore the lateral stiffness of
different sports wheelchair wheels commercially available to athletes in a ‘new’ and ‘used’
condition; and 2) determine the influence of (a) wheel stiffness, (b) tyre type (clincher vs.
tubular) and (c) tyre orientation on the physiological and biomechanical responses to
submaximal wheelchair propulsion and on maximal effort propulsion specific to wheelchair
basketball. It was hypothesised that stiffer wheels would result in reduced physiological
demand, since less energy would be dissipated through the wheel. Tubular tyres were
hypothesised to reduce rolling resistance through their higher inflation pressure, which was expected to minimise physiological demand and improve maximal effort sprinting performance. This effect was hypothesised to improve further still when the tyres were orientated optimally by an innovative wheel rim design.

**Methods**

**Participants**

Eight able-bodied (AB) males (age = 30 ± 5 years; body mass = 80.5 ± 9.1 kg; height = 1.81 ± 0.06 m) with previous experience of laboratory-based modes of wheelchair propulsion participated in the laboratory testing in the current study. A further three participants (age = 28 ± 8 years; body mass = 78.0 ± 10.0 kg) with extensive experience (≥ 6 years) of over-ground sports wheelchair propulsion participated in the field-based testing only. The study was approved by the local ethical committee and all participants provided their written, informed consent prior to testing.

**Wheels**

Three pairs of wheels currently available to wheelchair basketball players (i) Spinergy SLX, Spinergy Inc, San Diego, USA; (ii) Sun Equalisers, Sun Components, Milwaukee, USA; and (iii) Sun Classics, Sun Components, Milwaukee, USA; in both a ‘new’ and ‘used’ condition were investigated. In the used condition, spoke tensions were reduced and equated to the spoke tension of a 12 month old wheel, which were verified using a tensionmeter (Park Tool TM-1, Minnesota, USA). Each of these wheels were fitted with Kenda Kontender clincher tyres (Kenda, Ohio, USA), inflated to 110 psi.

Two further pairs of wheels (Spinergy SLX and Celeritas 300 wheel) equipped with tubular TUFO tyres (TUFO, Otrokovice, Czech Republic) were also investigated. TUFO tyres are manufactured using a silicon tread compound and do not contain an inner tube enabling a higher inflation pressure, which was controlled at 160 psi. As previously mentioned, the Celeritas 300 incorporates an innovative design at the wheel rim-tyre interface. The lateral wall of the rim is slightly higher in an attempt to orientate the tyre at an optimal position with the ground in a cambered wheelchair (Figure 1). The same chromium hand-rims
were used with each wheel configuration. Further details of each wheel are provided in Table 1.

Experimental Design

i) Wheel stiffness

The lateral stiffness of each wheel was examined using a deflection test (Figure 2). During the deflection tests the wheel was supported at three contact points on the inside of the wheel rim. Three incremental loads (5, 10 and 20 kg) were then applied to the axle of the wheel with the resulting deflection reported to the nearest 0.01 mm using a metric dial test indicator gauge (Toolzone, Devon UK). Each wheel was tested twice with the contact points in line with the spokes and twice with the contact points in between the spokes. Lateral stiffness, expressed in N mm\(^{-1}\), for each load and position was then averaged over 24 trials for each wheel. A higher value represents a stiffer wheel.

ii) Laboratory testing

Participants performed a series of 3-minute bouts on a dual-roller wheelchair ergometer (VPHandisport-25, Tecmachine, France) at two submaximal speeds (1.1 and 2.2 m s\(^{-1}\)). All testing was performed on a single roller to minimise resistance, which were equipped with two electromagnetic brakes, the sensors of which were calibrated using a known weight at the beginning of each day. Speed and torque signals sampled at 100 Hz. The same basketball wheelchair (RGK Quattro, Burntwood, UK; 26 inch wheels, 18° camber, 12.9 kg) was used for all wheel configurations. Since a total of sixteen, 3-minute bouts were to be performed (eight wheels, two speeds), each pair of wheels were tested in a randomised
order over two separate sessions within a two-week period to minimise the influence of fatigue.

Prior to each trial participants performed a deceleration test on the ergometer, whereby they accelerated the wheelchair over five pushes before allowing the wheels to decelerate to a standstill whilst sat upright and stationary. This enabled residual torque to be calculated, which is representative of rolling resistance. During each 3-minute trial participants averaged the desired speed, which was fed back in real time through a computer monitor (HP Compaq LA1951g, Hewlett Packard, California, USA) interfaced with the ergometer.

Data was collected during the final minute of each 3-minute trial. Power output was calculated using the average speed multiplied by the rolling resistance of the wheelchair-user combination. Expired air was collected using a breath-by-breath system (Cortex Metalyser 3B, Cortex, Leipzig, Germany), which had been calibrated at the beginning of each session using a known volume and concentration of gas. Respiratory data was recorded at 1 Hz, with oxygen uptake ($\dot{V}O_2$) averaged over the final minute. Heart rate was monitored using radio telemetry (RS400 Polar Sport Tester, Kempele, Finland) and was averaged over 5-second intervals. Push time and push frequency were also calculated during the final minute of each trial. Using a customised MATLAB programme, push time was calculated as the period of time during which a positive power output was produced. Push frequency was calculated by dividing the number of complete pushes during the final minute by the time elapsed. On completion of each 3-minute trial participants provided a measure of their localised, centralised and overall rating of perceived exertion (RPE) using a Borg scale [16]. A rest period of 3-minutes was provided between each trial to eliminate the effects of fatigue. To ensure fatigue was not present, the first trial of each session was repeated at the end, which verified the absence of fatigue.

### iii) Field testing

Each wheel configuration was also tested during maximal effort, on-court wheelchair propulsion, specific to wheelchair basketball on a separate occasion. Field testing was performed on the same indoor sports hall, fitted with wooden sprung flooring. Participants with experience of sports wheelchair propulsion (n = 3) performed two 20 m sprints from a
standstill in each wheel configuration. Wireless timing gates (Brower, Utah, USA) were positioned after 2.5 and 5 m to explore the influence of wheel configuration on initial acceleration and after 20 m to examine maximal sprinting performance. A 90-second rest period was enforced between each sprint.

Statistical Analysis

Means and standard deviations (SD) were computed for all variables during each wheel configuration. Data from the stiffness and laboratory-based testing was analysed using the Statistical Package for Social Sciences (SPSS vesion 21.0, Chicago, IL, USA) and was assessed for normality using Shapiro Wilk’s tests. A repeated measures analysis of variance (ANOVA) was used to determine whether lateral stiffness differed between wheel configurations. Significant main effects were explored using pairwise comparisons with a Bonferroni adjustment. Differences in stiffness when measured in line and in between spokes were examined using paired sample t-tests. A repeated measures ANOVA was performed for each laboratory-based measure to assess the effect of wheel configuration on submaximal wheelchair performance. Stiffness comparisons were made between and within new and used wheels. Tyre type comparisons were made between the new wheels with clincher tyres and the Spinergy TUFO and Celeritas 300 (both tubular), whilst tyre orientation comparisons were made between Spinergy TUFO and Celeritas 300. Pairwise comparisons were used to identify where any significant differences existed between wheel configurations using a Bonferroni adjustment. Effect sizes (ES) were calculated for statistically significant pairwise comparisons and were categorised as trivial (< 0.2), small (≥ 0.2 – 0.6), moderate (≥ 0.6 – 1.2), large (≥ 1.2 – 2.0) and very large (≥ 2.0) according to previous guidelines [17].

Results

i) Wheel stiffness

As demonstrated in Figure 3, lateral stiffness differed across wheel configurations (P < 0.0005). Pairwise comparisons identified a significant (P < 0.0005; ES = 7.6) reduction in lateral stiffness between the new (545.5 ± 20.1 N-mm⁻¹) and used (430.0 ± 7.4 N-mm⁻¹) Classic wheel. The new Classic wheel also elicited a significantly lower stiffness value than
both the new Spinergy (678.2 ± 102.1 N·mm⁻¹; \(P = 0.008; \text{ES} = 1.8\)) and Equaliser (579.7 ± 15.8 N·mm⁻¹; \(P < 0.0005; \text{ES} = 1.9\)) wheels. Similarly in a used condition, the Classics lateral stiffness was significantly lower than the used Spinergy (589.9 ± 23.6 N·mm⁻¹; \(P < 0.0005; \text{ES} = 9.1\)) and Equaliser (578.9 ± 13.0 N·mm⁻¹; \(P < 0.0005; \text{ES} = 14.1\)) wheels. The Celeritas 300 wheel differed in stiffness to all other wheel configurations. Greater stiffness was revealed in the Celeritas 300 wheel (456.3 ± 8.2 N·mm⁻¹) than the used Classic wheel (\(P < 0.0005; \text{ES} = 3.4\)), with reduced stiffness demonstrated in relation to all other wheel configurations (\(P < 0.0005; \text{ES} = 3.1\) to 11.3).

The Spinergy wheel was identified as the stiffest wheel tested, however as illustrated in Figure 3 large standard deviations were observed for this wheel in the new condition. This could be attributed to the significantly greater lateral stiffness (\(P = 0.002; \text{ES} = 4.6\)) observed for the new Spinergy wheel ‘in line’ compared to ‘in between’ spokes (Table 2). The Classic wheel also demonstrated significantly greater stiffness ‘in line’ with the spokes in both the new (\(P = 0.017; \text{ES} = 2.1\)) and used (\(P = 0.042; \text{ES} = 1.2\)) conditions.

Wheel configuration had a significant main effect on the residual torque and the power output of wheelchair propulsion at both low and high speeds (\(P < 0.0005\)). Residual torque and consequently the power output were significantly lower in both the tubular types, Spinergy TUFO and Celeritas 300, (\(P \leq 0.006; \text{ES} = \geq 2.36\)) compared to all other wheel configurations with clincher tyre types (Figure 4).
ii) Laboratory testing

Despite the differences in stiffness and residual torque, minimal differences in physiological and biomechanical parameters were observed between wheel configurations. A significant effect of wheel configuration on $\dot{\text{VO}}_2$ was observed at both low ($P = 0.001$) and high ($P = 0.018$) speeds (Figure 5). During the low speed, $\dot{\text{VO}}_2$ was significantly lower in the Celeritas 300 wheel ($0.60 \pm 0.11 \text{ L\cdot min}^{-1}$) than in the new Spinergy ($0.74 \pm 0.12 \text{ L\cdot min}^{-1}$; $P = 0.045$; ES $= 1.2$), used Spinergy ($0.75 \pm 0.11 \text{ L\cdot min}^{-1}$; $P = 0.047$; ES $= 1.4$) and used Equaliser ($0.74 \pm 0.10 \text{ L\cdot min}^{-1}$; $P = 0.049$; ES $= 1.3$). During the high speed, no statistically significant pairwise comparisons were identified between wheel configurations for $\dot{\text{VO}}_2$ although differences approaching significance existed between the Celeritas 300 wheel ($0.98 \pm 0.18 \text{ L\cdot min}^{-1}$) and both the used Spinergy ($1.19 \pm 0.19 \text{ L\cdot min}^{-1}$; $P = 0.056$; ES $= 1.1$) and Classic ($1.15 \pm 0.18 \text{ L\cdot min}^{-1}$; $P = 0.059$; ES $= 0.9$) wheel. No significant effect of wheel configuration was identified for heart rate during the low speed ($P = 0.349$). At the high speed, a significant main effect was observed for heart rate ($P = 0.020$), although no significant pairwise comparisons existed. Differences approaching statistical significance were again identified between the Celeritas 300 wheel ($94 \pm 11 \text{ beats\cdot min}^{-1}$) and the new ($101 \pm 9 \text{ L\cdot min}^{-1}$; $P = 0.066$; ES $= 0.7$) and used ($101 \pm 9 \text{ L\cdot min}^{-1}$; $P = 0.085$; ES $= 0.7$) Spinergy wheel. Wheel configuration had no significant bearing on localised, centralised and overall RPE, push time or push frequency at either speed.

iii) Field testing

The results of the 20 m sprints are displayed in Figure 6. The most noticeable differences in initial acceleration performance over 2.5 m (Figure 6a) and 5 m (Figure 6b) seemed to occur between the Spinergy wheels. The new Spinergy wheels displayed quicker times over 2.5 m ($1.24 \pm 0.10 \text{ s}$) and 5 m ($2.03 \pm 0.14 \text{ s}$) compared to the used Spinergy wheels ($1.29 \pm 0.09 \text{ s}$; $2.08 \pm 0.14 \text{ s}$ respectively). Yet at 20 m no differences appeared to exist (Figure 6c). The Equaliser wheels revealed the quickest times across all distances and the condition of this wheel (new or used) had little effect on performance. Finally, tubular
tyres did not appear to have a beneficial effect on linear sprinting performance. In fact, times were quicker in the new Spinergy, with clincher tyres, over 2.5 m (1.24 ± 0.10 s), 5 m (2.03 ± 0.14 s) and 20 m (5.72 ± 0.33 s) compared to the new Spinergy with tubular TUFO tyres (1.27 ± 0.14 s; 2.09 ± 0.23 s; 5.86 ± 0.38 s respectively). In the comparison of tyre orientation, the Spinergy TUFO demonstrated slightly quicker times than the Celeritas 300 wheel over 2.5 m (1.29 ± 0.15 s) and 5 m (2.12 ± 0.23 s), yet slower times over 20 m (5.77 ± 0.38 s).

FIGURE 6

Discussion

Wheels currently available to wheelchair basketball players differed in lateral stiffness. However, the impact that these wheels had on aspects of submaximal and maximal effort sports wheelchair propulsion were minimal. Alternatively, tyre type appeared to have more of an impact on performance, with high pressure tubular tyres shown to reduce rolling resistance and physiological demand. No further improvements in submaximal or maximal effort performance were established through innovative tyre orientations.

Wheel stiffness

The deflection tests revealed that Spinergy wheels were the stiffest (678.2 ± 102.1 N∙mm⁻¹) new wheels investigated. However, statistically significant differences were only identified in relation to the Classic and Celeritas 300 wheels. The fact that no significant difference was identified between the Spinergy and the Equaliser (579.7 ± 15.8 N∙mm⁻¹) wheels could be attributed to the large standard deviations observed for the new Spinergy’s. The Spinergy wheels were found to be significantly stiffer when measured in line with the spokes compared to in between spokes. The rationale for the greater stiffness in line with the spokes could be attributed to the different material, greater thickness or radial orientation of the spokes in a Spinergy wheel. The fact that lateral stiffness decreased in between spokes was likely to be related to the reduced number of spokes the Spinergy’s possessed (24) and subsequently the greater distances between spokes. Such a decrease in stiffness was not
observed in between spokes for the Equaliser, which contain double the number of spokes (48).

Despite this, it was clear that both the Spinergy and Equaliser wheels were significantly stiffer than the Classic and Celeritas 300 wheels in a new condition. Upon inspection of the specifications of each of these wheel configurations (Table 1), it was possible that the orientation of the spokes attributed to the differences observed. Both the Classic and Celeritas 300 wheels contained the same number (36) of spokes which were crossed (3x) on both sides of the wheel. Therefore the absence of radially orientated spokes, which were present on both sides in the Spinergy and on the inside of the Equaliser, could contribute to the lower stiffness. Gavin [8] revealed that the greater the number of spoke crossings, the lower the radial and lateral stiffness, which would support the aforementioned statement. Even though the Equalisers contain 4x crossings, this was only on the outside of the wheel and it appeared that the radial orientation of the inside spokes (0x) were sufficient for ensuring a stiff wheel. Gavin [8] also revealed that thicker spokes increased the radial and lateral stiffness of a bicycle wheel, which could further indicate the superior stiffness of the Spinergy wheel, which at 4mm, were far thicker than the steel spokes of all other wheel configurations.

A comparison of wheels in both a new and used condition revealed a decline in lateral stiffness in the Spinergy and Classic wheels in the used condition. Such deterioration was not observed for the Equalisers, which appeared to maintain their stiffness over time. These findings could again be explained by the number of spokes possessed by each wheel, whereby the wheel with the greater number of spokes maintains its stiffness over time even when the tension of individual spokes are reduced. However, this effect was exacerbated in wheels containing fewer spokes, where the distance between spokes obviously increases. This could have practical implications on wheelchair maintenance, as it would appear that constantly monitoring and maintaining spoke tension is more important in wheels with fewer spokes (Spinergy’s and Classic’s) than in wheels with a greater number of spokes (Equaliser’s).

Effects on performance
Despite the aforementioned differences in lateral stiffness between wheel configurations and the rationale for these differences, wheel stiffness appeared to have little effect on physiological demand or propulsion technique. The only physiological differences that existed between wheel configurations occurred in relation to the new Celeritas 300 wheel, which were equipped with high pressure tubular tyres. Of particular interest were the significant differences in $\dot{V}O_2$ identified at the low speed and the meaningful differences in heart rate observed at the high speed between the Celeritas 300 wheel and the new Spinergy. As previously mentioned, the new Spinergy was established as the stiffest wheel available, whereas the Celeritas 300 wheel was found to be the least stiff ($456.3 \pm 8.2$ N\cdot mm$^{-1}$) of the new wheels investigated. This would suggest that tyre type (and inflation pressure) has a far greater impact on performance than wheel stiffness. The fact that no further improvements in performance were achieved when the tubular TUFO tyre was tested in the stiffest wheel (Spinergy TUFO) confirmed this. Therefore minimising rolling resistance remains the critical factor in maximising pushing economy, which was not affected by lateral wheel stiffness, but was reduced in the higher pressure tubular TUFO tyres. This confirms the physiological benefits of higher tyre pressures that have previously been identified during daily life wheelchair propulsion [13-15] and highlights how important it is for athletes to constantly monitor their tyre pressure.

The results of the field-based testing revealed some interesting trends with regards to the effect of wheel configuration on initial acceleration and maximal effort linear sprinting performance. One of the most noticeable trends identified was the change in performance of the Spinergy wheels between the new and used condition. Over 2.5 m and 5 m, the new Spinergy wheel elicited quicker times than the used wheel, however no difference was observed at 20 m. It could therefore be interpreted that a stiffer wheel (new Spinergy) facilitates initial acceleration performance, but then a slightly more flexible wheel (used Spinergy) facilitates overall sprinting performance. Brandt [7] suggested that radial spokes cannot transmit torque as effectively as crossed spokes, as torque is only created once the hub rotates ahead of the rim, causing a small offset. This offset, which worsens when spoke tension is reduced, could lead to energy loss during the push and may account for the slightly impaired acceleration performance in the used Spinergy, where spoke tensions were reduced [7]. However, the same pattern was also observed in the Classic wheels, where the newer (stiffer) wheel appeared slightly quicker over short distances, yet similar over 20 m. Therefore, even though the Classic wheels had crossed spokes, the reduction in tension...
between the new and used condition may also bring about a loss in energy during initial
acceleration. Similarly the stiffer Spinergy TUFO was slightly quicker over 2.5 m and 5 m
compared to the Celeritas 300 wheel, also equipped with TUFO tyres. However, at 20 m this
pattern had reversed and the more flexible Celeritas 300 wheel displayed quicker times.
Explanations for the apparent improvement in linear sprinting after initial acceleration and
inertia had been overcome remain unclear and worthy of further investigation.

The wheel which appeared to perform the best across all distances of the 20 m sprint
was the Equaliser, where no real differences were seen between the new and used condition.
The fact that no differences were observed between the new and used Equaliser could be due
to the fact that these wheels did not differ in stiffness as previously mentioned. The only
plausible rationale for the apparent superior performance could be due to the greater
consistency in stiffness all around the Equaliser wheels, since no decline in stiffness was
established in between spokes. However, further research would again be required to explore
this association.

Contrary to the laboratory-based testing and what was originally hypothesised, the
tubular TUFO tyres did not seem to equate to beneficial on court performance. In fact it
appeared as if these high pressure tyres actually impeded linear sprinting performance since
times were slightly slower across all distances of the 20 m sprint in the Spinergy TUFO
compared to the new Spinergy with clincher tyres. Therefore, the greater tyre pressure of the
TUFO tyres (160 psi), which effectively reduced rolling resistance and physiological demand
in a laboratory environment, may have reduced the rolling resistance too much to allow for
effective performance in a sporting environment. It appeared as though the tyre pressure may
actually be too high (and the resistance too low) to enable sufficient traction between the tyre
and the surface to translate to successful on court performance. This is a slight concern given
that the TUFO tyres can be inflated to as much as 230 psi. It would appear that further
research is required to identify optimal tyre pressures, as there seems to be a point where high
pressure tyres that minimise rolling resistance and physiological demand become too high to
provide athletes with enough grip on a sports hall surface. As we already know from previous
literature the rolling resistance experienced in a sports wheelchair is lower during over-
ground propulsion on a basketball court surface compared to laboratory-based modalities [18].

Although tubular tyres elicited a positive effect on rolling resistance and physiological
demand and a slightly negative effect on linear sprinting performance, the introduction of an
innovative wheel rim design (Celeritas 300) appeared to have no further influence on
type performance. The Celeritas 300 was designed specifically for wheelchair sports with the
intention of orientating the tyre in a position that would reduce tyre deformation and
resistance in cambered sports wheelchairs. However, when compared to the Spinergy TUFO,
which was equipped with the same high pressure tubular tyres, no further reductions in
resistance or physiological demand were observed in the Celeritas 300. Despite this, athletes
who participated in the field testing did comment favourably on the performance of the
Celeritas 300. After completing the 20 m sprint, participants had to turn and return to the start
line for the next trial. It was during this manoeuvre that participants felt the Celeritas 300
excelled with turning at high speeds said to be facilitated. Obviously manoeuvrability
performance was not investigated during the current study, however such comments suggest
this may be a useful area for future investigation. Although tyre orientation did not
significantly reduce rolling resistance to the benefit of laboratory-based or linear court-based
propulsion, it may reduce turning resistance, which could benefit wheelchair basketball
players.

Future recommendations

Despite all of the interesting trends identified within the field-based testing, it must be
reiterated that a sample size of only 3 participants prevented any statistical analysis.
Therefore, future research with a larger sample of athletes would be warranted to confirm or
refute the initial findings presented. Based on what has been reported it would appear that
lateral wheel stiffness has little impact on submaximal pushing economy, however potential
improvements in initial acceleration performance could be achieved from a stiffer wheel.
Alternatively top-end sprinting performance appeared inhibited in stiffer wheels. Such
information could be extremely valuable to wheelchair manufacturers to identify the optimal
wheel configuration in terms of stiffness, tyre type / pressure and orientation to maximise all
areas of performance. Given that the aim of the current investigation was to explore a range
of wheels currently available, wheels differed in a number of spoke components. Therefore, it
may be beneficial for future testing to manipulate one area of wheel specification in isolation
to determine reliable cause and effect relationships between the intervention and performance.
Conclusions

The current study demonstrated that wheel configuration is an important consideration for wheelchair athletes. Although wheels currently available to athletes do differ in lateral stiffness, these differences have little effect on physiological demand. Whereas wheels with high pressure tubular tyres significantly reduced physiological demand through a lower rolling resistance. Therefore, it would appear that tyre type and pressure remain the most important aspects of wheel configuration for athletes to consider and maintain when purchasing a sports wheelchair.
Acknowledgements

The authors would like to thank RGK wheelchairs for their support and provision of equipment for the current study. Thanks are also extended to Loughborough Sports Technology Institute and Bob Budge for their assistance with data collection.

Figure Captions

Figure 1 – Illustration of the wheel rim design in a) the Celeritas 300 and b) standard Spinergy wheel and the tyre orientation of both wheels

Figure 2 – The experimental set-up of the deflection test used to assess lateral stiffness in each wheel configuration

Figure 3 – The effect of wheel configuration on lateral stiffness (means ± SD). Statistically significant differences are represented by:

* between new and used wheels

a new Spinergy

b new Equaliser
c used Spinergy
d used Equaliser
e all other wheel types

Figure 4 – The effect of wheel configuration on the residual torque and power output at two submaximal speeds of wheelchair propulsion (n = 8). All values are means ± SD.

*represents a significant difference to Celeritas 300

# represents a significant difference to Spinergy TUFO

Figure 5 – The effect of wheel configuration on oxygen uptake (top) and heart rate (bottom) during two speeds of wheelchair propulsion (n = 8). All values are means ± SD.

*represents a significant difference to Celeritas 300

Figure 6 – The effect of wheel configuration on linear sprinting performance over a) 2.5m; b) 5m and c) 20m during field based testing (n = 3). All values are means ± SD.

The diagram illustrates the comparison of power output (W) and residual torque (N\(\cdot\)m\(^{-1}\)) across different types of wheels: Spinergy, Equaliser, Classic, Spinergy TUFO, and Celeritas 300, under low and high conditions. The data shows a notable decrease in residual torque with increasing wheel usage.
