Abstract

In the one-way trading problem, a seller has \(L\) units of product to be sold to a sequence \(\sigma\) of buyers \(u_1, u_2, \ldots, u_\sigma\) arriving online and he needs to decide, for each \(u_i\), the amount of product to be sold to \(u_i\) at the then-prevailing market price \(p_i\). The objective is to maximize the seller’s revenue. We note that all previous algorithms for the problem need to impose some artificial upper bound \(M\) and lower bound \(m\) on the market prices, and the seller needs to know either the values of \(M\) and \(m\), or their ratio \(M/m\), at the outset.

This paper gives a one-way trading algorithm that does not impose any bounds on market prices and whose performance guarantee depends directly on the input. In particular, we give a class of one-way trading algorithms such that for any positive integer \(h\) and any positive number \(\epsilon\), we have an algorithm \(A_{h,\epsilon}\) that has competitive ratio \(O(\log \log r_{h,\epsilon})(\log \log (2r_{h,\epsilon})) \cdots (\log h r_{h,\epsilon})^1 + r_{h,\epsilon}\) if the value of \(r_{h,\epsilon} = p^*/p_1\), the ratio of the highest market price \(p^* = \max p_i\) and the first price \(p_1\), is large and satisfies \(\log h r_{h,\epsilon} > 1\), where \(\log^i x\) denotes the application of the logarithm function \(i\) times to \(x\); otherwise, \(A_{h,\epsilon}\) has a constant competitive ratio \(\Gamma_{h,\epsilon}\). We also show that our algorithms are near optimal by showing that given any positive integer \(h\) and any one-way trading algorithm \(A\), we can construct a sequence of buyers \(\sigma\) with \(\log h r_{h,\epsilon} > 1\) such that the ratio between the optimal revenue and the revenue obtained by \(A\) is \(\Omega(\log \log r_{h,\epsilon})(\log \log (2r_{h,\epsilon})) \cdots (\log h r_{h,\epsilon})^1 + r_{h,\epsilon}\)). A special case of the one-way trading is also studied, in which the \(L\) units of product is comprised of \(L\) items, each of which must be sold atomically (or equivalently, the amount of product sold to each buyer must be an integer).

Furthermore, a complementary problem to the one-way trading problem, say, the one-way buying problem, is studied in this paper. In the one-way buying problem, a buyer wants to purchase one unit of product through a sequence of \(n\) sellers \(v_1, v_2, \ldots, v_n\) arriving online, and she needs to decide the fraction to purchase from each \(v_i\) at the then-prevailing market price \(p_i\). Her objective is to minimize the cost. The optimal competitive algorithms whose performance guarantees depend only on the lowest market price \(p^* = \min p_i\), and one of \(M\) and \(\varphi\), the price fluctuation ratio, are presented.

1 Introduction

The one-way trading problem, which was introduced by El-Yaniv et al. [9, 10], involves selling a fixed amount of a product to a sequence of buyers, with the objective of maximizing the seller’s
revenue. A major difference between this problem and other general revenue maximization problems commonly studied in economics and computer science is that for the general problems, the seller has some control of the prices; he can determine the amount and the price of product to be sold to each buyer. However, for the one-way trading problem, a seller has no control of the prices, and when a buyer arrives, he can only determine the amount of the product to be sold at the then-prevailing market price. There are many applications that can be modeled as a one-way trading problem. One example is money-exchange\textsuperscript{1}, in which a seller has some initial asset, say US dollars, and he wants to sell them at the price of some target asset, say yen. The exchange rate fluctuates everyday. To maximize the amount of yen gained, the seller needs to decide, for each day, the right amount of US dollars to be changed at the exchange rate used on that day. Other applications such as stock selling in a stock market and electricity selling in a power grid can also be modeled naturally as one-way trading problem.

It is easy to solve the offline version of the problem; if the seller knows all the future prices, he can simply wait for the highest price and then sell all his product at that price. However, our problem is online in nature, and without knowledge of future prices, a player cannot be sure whether the current price is the highest. More formally, in our one-way trading problem, there is a seller who has $L$ units of product to be sold, and there is a sequence of buyers $u_1, u_2, \ldots, u_\sigma$ arriving. When a buyer $u_i$ arrives, the then-prevailing unit price $p_i$ is revealed and the seller needs to decide the amount $x_i$ of product to be sold to $u_i$ at price $p_i$, and the objective is to maximize $\sum_i p_i x_i$ subject to $\sum_i x_i \leq L$. The main features of the problem that make it difficult and interesting include: (1) he does not have any knowledge about the future prices, i.e., when $u_i$ arrives, he does not know any price $p_j$ where $j > i$, and (2) he needs to decide the amount of product to be sold to a buyer $u_i$ as soon as $u_i$ arrives.

Previous results.

After introducing the one-way trading problem, El-Yaniv et al. gave in [10] an algorithm for the problem that works under the assumption that there are a lower bound $m$ and an upper bound $M$ on the market prices such that $p_i \in [m, M]$ for all $p_i$, and that these bounds $m$ and $M$ are known to the algorithm. They proved that their algorithm has competitive ratio $O(\log(M/m))$, and showed that it is optimal by deriving a matching lower bound. They also studied the case when only the ratio $M/m$ is known, and gave an optimal algorithm for this case. More recently, Fujiwara et al. [11] have studied the one-way trading problem under the assumption that the input prices follow some given probability distribution. In [8], Chen et al. introduced the planning game problem, which is similar to the one-way trading problem, and they gave an algorithm for their problem which imposes some different constraint on the prices: instead of assuming that $p_i \in [m, M]$ for some price range $[m, M]$, their algorithm assumes that the difference between any two consecutive prices $p_i$ and $p_{i+1}$ is not too large, or more precisely, they assumed that for any $i$, $p_i / \beta \leq p_{i+1} \leq \alpha p_i$ for some fixed $\alpha, \beta > 1$. They showed that if there are $n$ buyers, their algorithm has competitive ratio $\frac{m \beta - (n-1)(\alpha + \beta) + (n-2)}{\alpha \beta - 1}$.

In [10], El-Yaniv et al. also studied another problem similar to the one-way trading problem, namely the $1$-$\max$-$\text{search}$ problem, in which there is a sequence of prices coming online, and when a price arrives, we have to decide immediately whether we accept the price or not. The objective is to accept the highest price. By assuming that all prices fall in the range $[m, M]$ and these bounds $m$ and $M$ are known, they gave an algorithm for this problem with competitive ratio $O(\sqrt{M/m})$, i.e., the ratio of the highest price and the price accepted by the algorithm is $O(\sqrt{M/m})$. In [14], Lorenz et al. generalized the $1$-$\max$-$\text{search}$ problem to the $k$-$\max$-$\text{search}$ problem, in which the objective is to accept the $k$ highest prices. By requiring that the bounds $m$ and $M$ are known, they gave an optimal algorithm for the problem, which has competitive ratio $\frac{\sqrt{k} - \sqrt{k-1}}{\sqrt{k-1}}\frac{\sqrt{M/m}}{\sqrt{k}}$.

\textsuperscript{1}In fact, the one-way trading problem is formulated as an money exchange problem in [9].
For recent related research on revenue maximization that allows price setting, we mention the auction problem [4, 13] and the pricing problem [1–3, 5–7]. For the auction problem, there are bidders competing for the products by sending their bids to the auctioneer, and the auctioneer chooses some bidders, and determines the price and amount of products to be sold to each chosen bidder. For the pricing problem, Zhang et al. have studied an interesting version in [16] in which the seller has m units of products to sell and each buyer has a valuation (i.e., price at which he is willing to buy) represented by a function \( v(x) \), which gives the valuation per unit if \( x \) units are purchased. When the highest valuation \( v^* \) is known, we gave an algorithm with competitive ratio \( O(\log v^*) \). Moreover, this algorithm was shown to be asymptotically optimal by giving a matching lower bound. Zhang et al. also studied in [17] an extension of this problem, in which there are multiple types of products and each user is interested in a particular bundle of products.

Our Contribution.
We note that previous work on the one-way trading problem needed to impose some constraints on how the prices fluctuate, e.g., there are a lower bound \( m \) and an upper bound \( M \) on the market prices such that \( p_i \in [m, M] \) for all prices. Furthermore, existing algorithms for the problem need to know some information about these constraints, such as the values of \( m \) and \( M \), or their ratio, in order to work correctly, (for example, the reservation price policy [10] accepts the first price \( \geq \sqrt{Mm} \)). In this paper, we give a one-way trading algorithm that does not need to impose any constraint on the market prices, and we derive a bound on its competitive ratio that depends directly on the input, or more precisely, depends on \( r^* = p^*/p_1 \), the ratio of the highest price \( p^* = \max p_i \) and the first price \( p_1 \) (in fact, our algorithm will treat \( p_1 \) as the lowest price and ignore any prices lower than \( p_1 \)). Furthermore, the algorithm does not make any assumption on the number of prices \( p_i \) in the input sequence and an adversary can terminate the sequence at any time by sending buyers with extremely low prices. In fact, we propose a generic one-way trading algorithm whose behavior depends on some given function \( f(x) \), which can be any function satisfying the following conditions: (i) It is non-increasing, and (ii) \( \int_1^\infty f(t)dt \) is bounded. Roughly speaking, \( f(x) \) helps us determine the amount of products the seller should sell at price \( x \). We show that by using \( f(x) \) in our generic algorithm, we have a one-way trading algorithm with competitive ratio \( O(\frac{1}{r^* f(r^*)}) \). Thus, to get a small competitive ratio, it suffices to find a \( f(x) \) that satisfies (i) and (ii), and \( f(x) \) is as large as possible. We observe that the following class of functions satisfies our requirements:

\[
\frac{1}{x \log x(\log^2 x) \ldots (\log^{(h-1)} x)(\log^h x)^{1+\epsilon}},
\]

where \( h \) is any positive integer and \( \epsilon \) is any positive real number, and where \( \log^h x \) denotes the function \( \log \log \ldots \log x \), which applies the logarithm function \( h \) times to \( x \). Based on these functions, (a different function for each different value of \( h \) and \( \epsilon \)) our generic algorithm gives us a class of one-way trading algorithms such that for any fixed positive integer \( h \) and positive number \( \epsilon \), we have an algorithm \( A_{h, \epsilon} \) such that when \( \log^h r^* > 1 \), \( A_{h, \epsilon} \) has competitive ratio \( O((\log r^*) \ldots (\log^{(h-1)} r^*) (\log^h r^*)^{1+\epsilon}) \); otherwise, its competitive ratio is bounded by some constant \( \Gamma_h \) depending only on \( h \). We also show that the bounds are almost tight by employing the divergence of the same class of function when \( \epsilon = 0 \) to design an adversary such that, given any online algorithm \( A \) for the problem, the adversary gives a sequence of buyers \( \sigma \) such that the ratio between the revenue obtained by an optimal offline algorithm on \( \sigma \) and that obtained by \( A \) is \( \Omega((\log r^*) \ldots (\log^{(h-1)} r^*) (\log^h r^*)) \) for any positive integer \( h \). Moreover, we show that our results still hold if the amount of products sold to each buyer is constrained to be at most a maximum amount specified by the buyer.

We also study a variant of the one-way trading problem in which the \( L \) units of product
are comprised of $L$ items, each of which must be sold atomically (in other words, the number of products the seller can sell must be an integer). We show that no online algorithm has competitive ratio less than $(r^*)^{1-\delta}$ for any $0 < \delta < 1$. We also show that for any integer $h > 0$ and real number $\epsilon > 0$ we have an algorithm $B_{h,\epsilon}$ for this atomic one-way trading problem that has competitive ratio $O(r^*)$. Besides being near optimal, $B_{h,\epsilon}$ is interesting in that, as long as the seller does not sell all his products, $B_{h,\epsilon}$ guarantees that the ratio between the maximum offline revenue and the current revenue of the seller up to that moment is no more than $O((\log r^*) \cdots (\log^{(h-1)} r^*)(\log^h r^*)^{1+\epsilon})$ if $\log^h r^* \geq 1$, and has constant competitive ratio otherwise. This means that whenever the seller has products to sell and thus can still participate in the market, he is still competitive. Furthermore, we show that if the seller knows an upper bound $U$ of $r^*$, we have an online algorithm with competitive ratio $(U)^{1/L}L$ if $L < \log U$, and $O(\log U)$ otherwise, where $L$ is the total number of products that the seller can sell; and we derive a lower bound of $((U)^{1/L} - 1)L$. Note that when $L$ is sufficiently large, the algorithm can achieve an optimal bound of $O(\log U)$.

The complementary problem to the one-way trading problem is the one-way buying problem, in which a buyer wants to purchase one unit of product through a sequence of $n$ sellers $v_1, v_2, \ldots, v_n$ arriving online, and she needs to decide the fraction to purchase from each $v_i$ at the then-prevailing market price $p_i$. Her objective is to minimize the cost. The one-way buying problem is a special case of the inventory problem, which has also a rich literature. Among others, Golabi [12] investigated the case where the purchase prices are from a known distribution. Note that different from the one-way trading problem, in which the seller gains no revenue if doing nothing, the buyer in the one-way buying problem will be penalized for the un-purchased amount, at the highest market price. Therefore, either the price upper bound $M$ or the price fluctuation ratio $\varphi$ must be known ahead. We present optimal competitive algorithms whose performance guarantees depend only on the lowest market price $p^* = \min_i p_i$, and one of $M$ and $\varphi$.

## 2 Fractional Products

### 2.1 Upper bound

Since products could be sold fractionally, we may assume, without loss of generality, that the seller has one unit of product to sell. The offline version is easy to solve: the whole product is assigned to the buyer with the highest market price. However, for the online version, we have no information about the future prices, including the bound of the highest market price. If the whole amount of product has been sold at some time, and then a buyer with very high market price arrives, the performance will be poor. Thus, we must keep or reserve some amount in case there is a future buyer with a higher market price. On the other hand, if we reserve too much for the possible buyer with higher market price and assign very little to the buyers who have come already, the performance will be also poor since the possible buyer with higher price may not come. Thus, to have a good performance, the amount sold and the amount remaining should be balanced nicely.

For the purposes of illustrating the main ideas of our algorithm only, consider the case when all prices are non-negative integers: in general, our algorithm is not restricted to integer prices. We make the following observations.

- Our algorithm should only sell products when the price is strictly higher than the maximum price that we have seen so far. For example, suppose the input sequence of prices is 1, 4, 2, 3, 6, 5, 12. We can ignore the prices 2, 3, 5 and do not sell any at these prices because the optimal offline algorithm will ignore these prices anyway; if our solution is
competitive for the input 1, 4, 6, 12, it will also be competitive for the input 1, 4, 2, 3, 6, 5, 12. Therefore, we can focus on handling price sequences that are strictly increasing.

- If we have a good solution for a sequence of strictly increasing and consecutive prices, i.e., for the price sequence 1, 2, 3, ..., $p^*$, then we can easily modify it to get a good solution for any price sequences that are strictly increasing with the highest price $p^*$. For example, suppose that for the prices 1, 2, 3, 4, our algorithm sells an amount $\delta_1, \delta_2, \delta_3, \delta_4$ of products at prices 1, 2, 3, 4, respectively and thus obtains a revenue of $R = \delta_1+2\delta_2+3\delta_3+4\delta_4$. Then, for the strictly increasing price sequence 1, 3, 4, we can sell an amount of $\delta_1$ at price 1, $\delta_2+\delta_3$ at price 3, and $\delta_4$ at price 4. Then, the revenue we obtain is $\delta_1+3(\delta_2+\delta_3)+4\delta_4 \geq R$.

Therefore, our algorithm can focus on strictly increasing and consecutive price sequences. For these sequences, we only need to determine the amount $\delta_i$ of products to be sold at price $p_i$. Since there is only one unit of product, we must have $\sum_{i=1}^{\infty} \delta_i \leq 1$. Another property that is desirable is that the $\delta_i$s should be decreasing, i.e., $\delta_1 > \delta_2 > \delta_3 > \ldots$; the leading $\delta_i$s should be large so that we can sell enough products if the market crashes very early, i.e., the adversary declares immediately that there are no more buyers, or buyers with extremely low market prices. Then, for any input price sequence with highest value $p^*$, our algorithm will have revenue at least $\delta_1+2\delta_2+\ldots+p^*\delta^* \geq (p^*)^2\delta^*/2$, and since no algorithm (including the offline optimal algorithm) can have revenue higher than $p^*$, the competitive ratio of this algorithm is $O(1/(p^*\delta^*))$ (Lemma 1).

Now we give the algorithm. The algorithm assigns amounts based on a non-increasing function $f(x)$, which computes the value of $\delta_i$ such that $\int_0^{+\infty} f(x)dx = 1$, $\int_0^1 f(x)dx = \delta_1$, $\int_1^2 f(x)dx = \delta_2$, ..., $\int_{i-1}^i f(x)dx = \delta_i$.

Let $(p_1, p_2, ..., p^*)$ be the sequence of strictly increasing transacted prices, i.e. prices at which the seller sells some (non-zero) amount to the buyer. For ease of analysis, we can normalize this sequence to be $(r_1, r_2, ..., r^*) = (p_2/p_1, ..., p^*/p_1)$ where the first price $r_1$ is 1 and the normalized maximum $r^*$ is the ratio of the highest transacted price $p^*$ to the lowest transacted price $p_1$. Any buyers with market price less than $p_1$ will be ignored. For the sake of simplicity, we shall denote $r_i$ as the normalized price of the $i$-th buyer and $r^*$ as the highest normalized price. The online selling strategy is described below as Algorithm 1. Note that Algorithm 1 can handle non-integer prices.

**Algorithm 1 : Online Selling**

Initially, let $cr^* \leftarrow 0$. \hspace{1cm} $\triangleright cr^*$ is the current highest normalized price.

repeat

when a buyer with normalized market price $r$ comes

if $r > cr^*$ then

Assign $\int_{cr^*}^r f(x)dx$ products to this buyer.

$cr^* \leftarrow r$

end if

until no buyer comes

---

**Lemma 1.** Suppose $r^*$ is the highest normalized market price, if $f(\cdot)$ is a non-increasing function, the competitive ratio is at most $O(1/r^*\cdot f(r^*))$.

**Proof.** The revenue received from Algorithm 1 is $r_1 \int_0^{r_1} f(r)dr + r_2 \int_{r_1}^{r_2} f(r)dr + \ldots + r^* \int_{r^*}^{r^*} f(r)dr \geq \int_0^{r^*} r \cdot f(r)dr$ where $r^*$ is the second highest normalized market price in the sequence.

---

2The decreasing of $\delta_i$ can be argued easily. WLOG, assume that $p_1 < p_2$ and $\delta_1 \leq \delta_2$, we can show that the competitive ratio can be decreased by moving a small amount from $\delta_2$ to $\delta_1$. This process can continue until $\delta_1 > \delta_2$. 

---
Since $f(r)$ is non-increasing, the revenue received from Algorithm 1 is at least $\int_0^{r^*} r \cdot f(r) dr \geq f(r^*) \int_0^{r^*} r dr = f(r^*) \cdot \frac{(r^*)^2}{2}$. Note that the maximum revenue is $r^*$ given that the seller has only one unit to sell, and therefore, the competitive ratio is at most $\frac{\int_0^{r^*} r \cdot f(r) dr}{O(r^* \cdot f(r^*))}$. 

In order to get a good performance, we need to find a non-increasing function $f(x)$ such that $\int_0^\infty f(x)dx$ converges to 1, or more simply, $\int_0^\infty f(x)dx = c$ for some constant $c$ (as we can normalize it to 1 later), and for any $x > 1$, $f(x)$ is as large as possible. After assuming the first market price is 1, we may just analyze the property of $x > 1$, normalize it to 1 later), and for any $f$ for any real number $h,\epsilon$.

**Proof.**

By induction on $i$. When $i = 0$, $b_0 = 1$, it is easy to see that for any $\epsilon > 0$, $f(x)$ converges if and only if $\epsilon > 0$, for $\epsilon = 1/(x \cdot x^\epsilon)$ is too small. This suggests that $f(x) = 1/(x \xi(x))$ where $\xi(x)$ is an increasing function and $\xi(x) = o(x^\epsilon)$ for any $\epsilon > 0$. A good candidate for $\xi(x)$ is a poly-log function of $x$. This motivates us to focus on the class of functions $f(x) = 1/(x \log x \log^2 x \ldots (\log^i x)^{1+\epsilon})$ where $\epsilon > 0$ and $\log^i x$ denotes the application of the logarithm function $i$ times to $x$, where $i \geq 0$. Now we define the class of functions formally.

**Definition 1.** Assume real number $\epsilon \geq 0$, integer $i \geq 0$, $b_0 = 1$, and $b_{i+1} = e^{b_i}$, define function $q_{i,\epsilon}(x)$ for $x \geq b_i$ as follows.

$$q_{i,\epsilon}(x) = \begin{cases} 
  x^{1+\epsilon} & \text{if } i = 0 \\
  x \cdot q_{i-1,\epsilon}(\ln x) & \text{if } i > 0 
\end{cases}$$

Thus, $q_{1,\epsilon}(x) = x \cdot (\ln x)^{1+\epsilon}$, $q_{2,\epsilon}(x) = x \cdot (\ln x) \cdot (\ln^2 x)^{1+\epsilon}$, and $q_{i,\epsilon}(x) = x \cdot (\ln x)^{i+\epsilon}$. The following lemma gives the condition when $\int_{b_i}^{+\infty} \frac{1}{q_{i,\epsilon}(x)}dx$ converges.

**Lemma 2.** For each integer $i \geq 0$, $\int_{b_i}^{+\infty} \frac{1}{q_{i,\epsilon}(x)}dx$ converges if and only if $\epsilon > 0$, in particular, $\int_{b_i}^{+\infty} \frac{1}{q_{0,0}(x)}dx$ diverges.

**Proof.** By induction on $i$. When $i = 0$, $b_0 = 1$, it is easy to see that $\int_{b_0}^{+\infty} \frac{1}{q_{0,\epsilon}(x)}dx = \int_1^{+\infty} \frac{1}{x^{1+\epsilon}}dx$ converges if and only if $\epsilon > 0$. Assume that the hypothesis is true for $i - 1$. As $b_i = e^{b_{i-1}}$, we have $\int_{b_i}^{+\infty} \frac{1}{q_{i,\epsilon}(x)}dx = \int_{e^{b_{i-1}}}^{+\infty} \frac{1}{x q_{i-1,\epsilon}(\ln x)}dx = \int_{b_{i-1}}^{+\infty} \frac{1}{q_{i-1,\epsilon}(y)}dy$, where $y = \ln x$. Thus, $\int_{b_i}^{+\infty} \frac{1}{q_{i,\epsilon}(x)}dx$ converges if and only if $\epsilon > 0$. 

The following theorem shows the competitive ratio of Algorithm 1 by constructing $f(x)$ from $q_{i,\epsilon}(x)$, i.e., proving that the area under $f(x)$ when $x > 0$ is bounded and $f(x)$ is non-increasing and defined for all $x > 0$.

**Theorem 1.** Suppose $r^*$ is the highest normalized market price, there exists an online algorithm $A_{h,\epsilon}$ for the unbounded one-way trading problem with competitive ratio $O(1)$ if $r^* < b_h$ and $O(q_{h-1,\epsilon}(\log r^*))$ if $r^* \geq b_h$ for any fixed positive integer $h$ and any real number $\epsilon > 0$.

**Proof.** For any fixed positive integer $h, b_h$ is a constant such that $\ln(b_h) = 1$. From Lemma 2, for any real number $\epsilon > 0$, suppose $\int_{b_h}^{+\infty} \frac{1}{q_{h,\epsilon}(x)}dx$ converges to a constant $c$. As $\ln(b_h) = 1$ when $x \geq b_h$, we define function $f_{h,\epsilon}(x)$ as follows.

$$f_{h,\epsilon}(x) = \begin{cases} 
  \frac{1}{b_h + c \cdot q_{h,\epsilon}(b_h)} & \text{if } 0 < x < b_h \\
  \frac{b_h + c \cdot q_{h,\epsilon}(b_h)}{b_h + c \cdot q_{h,\epsilon}(b_h)} \cdot \frac{1}{q_{h,\epsilon}(x)} & \text{if } x \geq b_h 
\end{cases}$$

It can be verified that $\int_0^{+\infty} f_{h,\epsilon}(x)dx = 1$ and $f_{h,\epsilon}(x)$ is non-increasing (since $f_{h,\epsilon}(x) = f_{h,\epsilon}(b_h)$ is a constant when $0 < x < b_h$ and $f_{h,\epsilon}(x)$ is decreasing when $x \geq b_h$), i.e., $f_{h,\epsilon}(x)$, which depends on $h$ and $\epsilon$, satisfies the requirement of Algorithm 1, which gives $A_{h,\epsilon}$. By Lemma 1, we can analyze the competitive ratio w.r.t. the highest market price $r^*$. 

6
• If \( r^* < b_h \), the competitive ratio is \( O\left(\frac{b_h + c q_h}{r^*}\right) \), which is \( O(1) \).
• If \( r^* \geq b_h \), the competitive ratio is \( O\left(\frac{1}{r^* f_{h,s}(r^*)}\right) \), which is \( O(q_{h-1},(\log r^*)) \), i.e., \( O(\log r^* \log^{(2)} r^* \ldots (\log^{(h)} r^*)^{1+\epsilon}) \).

2.2 Lower bound

In this part, we present a lower bound for the competitive ratio of the unbounded one-way trading problem. We will show that the lower bound and the upper bound given in Section 2.1 are almost match; in other words, Algorithm 1 is near optimal.

To derive a lower bound on the competitive ratio, we give an adversary that determines the sequence of prices \( p_1, p_2, p_3, \ldots \) and whenever the seller has sold some products, the adversary checks the total revenue the seller has accumulated so far, and if it is not competitive, the adversary declares immediately that there are no more buyers, or buyers with extremely low market price, i.e., the market “crashes”. The prices \( p_i \)’s grow exponentially, i.e., \( p_i = \Theta(e^i) \). The adversary also determines for each \( i \) a bound \( \Delta_i \), which is the minimum amount of product sold during the first \( i \) prices in order to prevent the market crashes. In other words, if the amount of product sold at price \( p_1, p_2, \ldots, p_k \) are \( s_1, s_2, \ldots, s_k \), respectively, and \( s_1 \geq \Delta_1, s_1 + s_2 \geq \Delta_2, \ldots, \sum_{k=1}^{i-1} s_k \geq \Delta_{i-1}, \text{ and } \sum_{k=1}^{i} s_k < \Delta_i \), the market crashes immediately at price \( p_i \). Note that in such case, the seller has sold at most \( \Delta_j - \Delta_{j-1} \) unit of product at \( p_j \), and since \( p_j \) is much larger than all previous prices, we would be able to show that the total revenue obtained by the seller will be dominated by the last transaction and is \( O((\Delta_j - \Delta_{j-1})p_j) \). On the other hand, an offline algorithm can sell the whole unit of product at \( p_j \) and gets the maximum revenue \( p_j \). Thus the competitive ratio of the algorithm is \( \Omega\left(\frac{1}{\Delta_j - \Delta_{j-1}}\right) \) if the adversary “crashes” the market after \( p_j \). The challenge for getting a large lower bound is to decide the \( \Delta_i \)'s such that (i) they are unbounded (i.e., \( \Delta_i \to \infty \) when \( i \to \infty \)) so that the seller will fail eventually to meet the requirement on the minimum amount of product sold, and (ii) \( \Delta_i - \Delta_{i-1} \) is as small as possible. The bound \( \Delta_i = \frac{1}{c+1} + \frac{1}{c+2} + \cdots + \frac{1}{c+i} \) can be considered as a good candidate, which will lead us to a lower bound of \( \Omega(i) \) or \( \Omega(\log p_i) \) when the highest price \( p_i = O(e^i) \). Below, we describe some other \( \Delta_i \)'s that will lead us to a substantially larger bound.

From Lemma 2, we know that \( q_{h,0}(x) \) is a good candidate such that there is a \( b_h > 0 \) causing \( \int_{b_h}^{+\infty} \frac{1}{q_{h,0}(x)} \) to diverge, where \( \ln^{(h)} b_h = 1 \). The adversary in Algorithm 2 uses \( \sum_{k=1}^{j} \frac{1}{q_{h,0}(b_h + k - 1)} \) as a candidate for \( \Delta_j \) as mentioned before and \( s_j \) is the amount of products assigned to buyer \( u_j \). Since \( 1/q_{h,0}(x) \) is monotone decreasing and \( \int_{b_h}^{+\infty} \frac{1}{q_{h,0}(x)} \) diverges for any fixed integer \( h > 0 \), the sum \( \sum_{k=1}^{\infty} \frac{1}{q_{h,0}(b_h + k - 1)} \) diverges. Therefore, Algorithm 2 must be terminated on some buyer since the seller has only one unit of product.

\textbf{Algorithm 2 : Adversary for online selling}

Assume that the seller has one unit of product to sell.

Let \( j \leftarrow 0 \).

repeat

Let \( j \leftarrow j + 1 \).

Send buyer \( u_j \) with market price \( e^{b_h + j - 1} \) to the seller.

The seller sells \( s_j \) product to buyer \( u_j \),

until \( \sum_{k=1}^{j} s_k \leq \sum_{k=1}^{j} \frac{1}{q_{h,0}(b_h + k - 1)} \)

Assume the adversary stops sending buyers after the arrival of buyer \( u_j \). From Algorithm 2,
the total revenue received is \( \sum_{k=1}^{j} s_k \cdot e^{b_h+k-1} \), while the maximum offline revenue is \( e^{b_h+j-1} \).

The following lemma estimates the total revenue received from Algorithm 2.

**Lemma 3.** \( \sum_{k=1}^{j} s_k \cdot e^{b_h+k-1} = O(\frac{e^{b_h+j-1}}{q_h,0(b_h+j-1)}) \)

**Proof.** From the adversary’s strategy, at any step \( j' < j \), \( \sum_{k=1}^{j'} s_k > \sum_{k=1}^{j'}\frac{1}{q_h,0(b_h+k-1)} \), and in the last step \( j \), \( \sum_{k=1}^{j} s_k \leq \sum_{k=1}^{j} \frac{1}{q_h,0(b_h+k-1)} \). Therefore, \( \sum_{k=1}^{j} s_k \cdot e^{b_h+k-1} \leq \sum_{k=1}^{j} \frac{e^{b_h+k-1}}{q_h,0(b_h+k-1)} \).

In Lemma 5 (see Appendix), we show that \( \frac{e^{b_h+k}}{q_h,0(b_h+k)} \cdot \frac{q_h,0(b_h+k-1)}{e^{b_h+k-1}} = \frac{e^{b_h,0(b_h+k-1)}}{q_h,0(b_h+k-1)} \geq c \) for some constant \( c > 1 \) and any \( k \geq 1 \). Thus, \( \sum_{k=1}^{j} s_k \cdot e^{b_h+k-1} \leq \frac{e^{b_h+j-1}}{q_h,0(b_h+j-1)} \cdot \frac{1}{1-1/c} = O(\frac{e^{b_h+j-1}}{q_h,0(b_h+j-1)}) \).

Based on the above analysis, Theorem 2 gives the lower bound on the competitive ratio of the unbounded one-way trading problem.

**Theorem 2.** The competitive ratio of the unbounded one-way trading problem is at least \( \Omega(q_h,0(\log r^*)) = \Omega(\log r^* \cdot \log(2) r^* \cdots \log(h+1) r^*) \) where \( r^* \) is the highest normalized market price and \( h > 0 \) is any fixed integer.

**Proof.** Assume that Algorithm 2 terminates on some buyer \( u_j \). As mentioned before, the revenue received from Algorithm 2 is \( \sum_{k=1}^{j} s_k \cdot e^{b_h+k-1} = O(\frac{e^{b_h+j-1}}{q_h,0(b_h+j-1)}) \) (Lemma 3), and the maximum offline revenue is \( e^{b_h+j-1} \) by assigning the whole product to buyer \( u_j \) with the market price \( e^{b_h+j-1} \). As \( p^* = e^{b_h+j-1} \), the performance ratio is at least \( \Omega(q_h,0(b_h+j-1)) = \Omega(\log p_j \log(2) \log(h+1) p_j)) = \Omega(\log r^* \log(2) r^* \cdots \log(h+1) r^*) \) since \( b_h \) can be regarded as a constant and \( r^* = p_j/p_1 = e^{j-1} \).

### 2.3 Buyers with Bounded Quotas

Now we consider the case where each buyer has a maximum amount of products he wants to buy at the market price. This variant can be regarded as an extension of the previous part. Algorithm 1 assigns products only based on the buyer’s market price with no regard for how much the buyer is able to buy, i.e., the buyer’s quota. Algorithm 3 is a modification of Algorithm 1 taking into consideration the buyer’s quota. The assigned amount is the amount the buyer’s quota or the amount the seller wants to sell, whichever is less. After assignment, we modify the value \( r^j \) such that \( \int_0^{r^j} f(x)dx \) is the current total amount of products sold to buyers.

**Algorithm 3 : Online Selling with Bounded Quotas**

Initially, let \( r^j \leftarrow 0 \).

repeat

when a buyer comes with market price \( r \) and quota \( q \)

if \( r > r^j \) then

Assign \( \delta = \min\{\int_{r}^{r^j} f(x)dx, q\} \) products to this buyer.

\( r^j \leftarrow \arg \min \int_{r}^{r^j} f(x)dx = \int_{r}^{r^j} f(x)dx + \delta \)

end if

until no buyer comes

**Lemma 4.** The total revenue received using Algorithm 3 is no less than \( \int_0^{r^j} xf(x)dx \).

**Proof.** Let \( \int_{r_i}^{r_{i+1}} f(x)dx \) be the amount of products sold to buyers \( u_i \) with market price \( r_i \), where \( r'_0 = 0 \). As \( r_i \geq r_{i+1} \), the total revenue achieved by Algorithm 3 is at least \( r_1 \cdot \int_{r_1}^{r_2} f(x)dx + r_2 \cdot \int_{r_2}^{r_3} f(x)dx + \cdots \geq \int_0^{r^j} xf(x)dx \). \( \square \)
Theorem 3. For the unbounded one-way trading problem, if each buyer has a maximum amount of products he wants to buy at the market price, there is an online selling strategy with competitive ratio $O(1)$ if $r^* < b_h$ and $O(q_{h-1,c}(\log r^*))$ if $r^* \geq b_h$ for any fixed integer $h$ and any real number $c > 0$, where $r^*$ is the highest normalized market price.

Proof. After all buyers have been considered, we have $r'$ and $r^*$ such that the total amount of sold products is $\int_{b'}^{r^*} f(x)dx$ and $r^*$ is the highest normalized market price among all buyers. Since each buyer has a quota, the optimal offline revenue $OPT$ might not have all products sold at the highest market price $r^*$ and some products might be sold with price less than $r^*$ or even $r'$.

Partition the optimum revenue $OPT$ into two parts: $OPT_1$ and $OPT_2$ denote the total revenues received from buyers whose market prices are no higher than $r'$ and higher than $r'$ respectively. Let $ALG$ be the total revenue received from Algorithm 3, and the competitive ratio is $\frac{OPT}{ALG} = \frac{OPT_1}{ALG} + \frac{OPT_2}{ALG}$.

As $ALG \geq \int_{b'}^{r^*} xf(x)dx$ (by Lemma 4) and $OPT_1 \leq r'$ (since buyers’ market prices w.r.t. $OPT_1$ are no more than $r'$), from previous analysis as given in Theorem 1, by letting $f(x) = q_{h,c}(x)$ for a fixed $h$ and $c > 0$,

- if $r' < b_h$, $\frac{OPT_1}{ALG}$ is a constant,
- if $r' \geq b_h$, $\frac{OPT_1}{ALG}$ is at most $O(q_{h-1,c}(\log r'))$, which is upper bounded by $O(q_{h-1,c}(\log r^*))$ as $r' \leq r^*$.

For any buyer with market price $r$ higher than $r'$ and with quota $q$, Algorithm 3 assigns $q$ products with price $r$ to this buyer. Those buyers whose market prices are between $r'$ and $r^*$ would take the maximum amount they want to buy. Otherwise, the assigned amount less than $q$ leads to a contradiction from the value of $r'$. Thus, $OPT_2 \leq ALG$.

Given the above analysis, the competitive ratio of Algorithm 3 for the unbounded one-way trading problem with bounded quotas is at most $O(q_{h-1,c}(\log r^*))$ if $r^* \geq b_h$ for any fixed integer $h > 0$ and $c > 0$, or $O(1)$ if $r^* < b_h$. $\square$

3 Atomic Products

In this section, we consider the case where the seller has $L$ products (i.e., $L$ items of a product), which must be sold atomically, i.e., the product cannot be sold fractionally.

3.1 The Highest Normalized Price $r^*$ is Unbounded

Since the products cannot be sold fractionally and the amount $L$ is fixed, no algorithm can guarantee that every buyer with a higher market price will be sold a non-zero number of products. Note that the highest market price $r^*$ is unknown and the difference in market prices between buyers can be arbitrarily large. Therefore, when the seller does not satisfy a buyer or exhausts all his products, the performance ratio can be arbitrarily large. However, before the seller exhausts all his $L$ products, especially when $L$ is large enough, we still have a selling strategy with good competitive ratio. This selling strategy is similar to Algorithm 1 as given in Section 2.1 by approximating the function $f_{h,c}(x)$ as defined in Theorem 1,

$$f_{h,c}(x) = \begin{cases} 
\frac{1}{b_h + c q_{h,c}(b_h)} & \text{if } 0 < x < b_h \\
\frac{1}{b_h + c q_{h,c}(b_h)} \cdot \frac{1}{q_{h,c}(x)} & \text{if } x \geq b_h 
\end{cases}$$

where $\ln^{(h)} b_h = 1$, $c = \int_{b_h}^{+\infty} \frac{1}{q_{h,c}(x)} dx$, and $q_{h,c}(b_h)$ is defined in Definition 1. From previous analysis as given in Theorem 1, we know $\int_0^{+\infty} f_{h,c}(x)dx = 1$ and $f_{h,c}(x)$ is non-increasing when
$x > 0$. The algorithm is described as follows. Again, in the following algorithm and analysis, the market prices are normalized as in Algorithm 1, i.e., $r_1 = 1, \ldots, r^* = p^*/p_1$ for actual prices $p_1, \ldots, p^*$.

Algorithm 4 (B<sub>h,ε</sub>) : Online Atomic Selling

<table>
<thead>
<tr>
<th>Let $c_r^* \leftarrow 0.$</th>
</tr>
</thead>
<tbody>
<tr>
<td>Let $R \leftarrow L$</td>
</tr>
<tr>
<td>repeat</td>
</tr>
<tr>
<td>When a buyer with normalized market price $r$ comes,</td>
</tr>
<tr>
<td>if $r &gt; c_r^*$ then</td>
</tr>
<tr>
<td>Sell $\text{min}{R, [L \cdot \int_{c_r^*}^{r} f_{h,\epsilon}(x)dx]}$ with price $r$ to the buyer.</td>
</tr>
<tr>
<td>$c_r^* \leftarrow r$</td>
</tr>
<tr>
<td>$R \leftarrow R - \text{min}{R, [L \cdot \int_{c_r^*}^{r} f_{h,\epsilon}(x)dx]}$</td>
</tr>
<tr>
<td>end if</td>
</tr>
<tr>
<td>until no buyer comes</td>
</tr>
</tbody>
</table>

In Theorem 4, we show that before the seller has exhausted all his products, Algorithm $B_{h,\epsilon}$ has a good competitive ratio and it is at most $r^*$ under all circumstances.

**Theorem 4.** (Upper bound) The unbounded one-way trading problem admits an online algorithm with competitive ratio $O(q_{h,\epsilon}(\log r^*))$ (when $r^* \geq b_h$) or $O(1)$ (when $r^* < b_h$) before the seller has sold all his products, and its competitive ratio is at most $r^*$ under all circumstances.

**Proof.** Before the seller has sold all his products, Algorithm $B_{h,\epsilon}$ will sell $\lfloor L \cdot \int_{c_r^*}^{r} f_{h,\epsilon}(y)dy \rfloor$ products, which is at least $\int_{c_r^*}^{r} f_{h,\epsilon}(y)dy$ of his holdings, to a buyer with market price $r$. Thus, the competitive ratio $O(q_{h,\epsilon}(\log r^*))$ or $O(1)$ as given in Theorem 1 still holds.

On the other hand, if the seller has exhausted all his products, he cannot satisfy the next buyer with market price $r^*$, which can be arbitrarily large. In this case, the maximum offline revenue is $Lr^*$ while the revenue received from the algorithm is at least $L$, and thus, the competitive ratio is at most $r^*$.

**Theorem 5.** (Lower bound) The unbounded one-way trading problem does not admit any online algorithm with competitive ratio less than $(r^*)^{1-\delta}$ for any $0 < \delta < 1$ if the products are atomic.

**Proof.** We use an adversary argument. Let $\delta$ be a real number, $0 < \delta < 1$. The adversary sends at most $L + 1$ buyers sequentially. For $i = 1, 2, \ldots$, the market price of the $i$-th buyer $u_i$ is $r_i$. Specifically, $r_1 = 1$, and for $i \geq 2$ we have $r_i = r_{i-1}^{1/\delta}$ such that $r_i/r_{i-1} = r_{i-1}^{1-\delta}$. As long as the seller sells at least one product to $u_i$, the adversary continues to send the next buyer $u_{i+1}$ with an increased price. Otherwise, if nothing is sold to $u_i$, the adversary stops sending more buyers.

Let $u_{l+1}, 1 \leq l \leq L$, be the last buyer (who is unsatisfied) sent by the adversary, i.e., $r^* = r_{l+1}$. Then the revenue of the optimal offline strategy is $Lr_{l+1}$ while the revenue received by the seller is at most $Lr_l$. The ratio is at least $r_{l+1}/r_l = r_{l+1}^{1-\delta} = (r^*)^{1-\delta}$. □

3.2 The Highest Normalized Price $r^*$ is Bounded

If the seller has some extra information about the market price such as the ratio between the highest market price and the first market price is upper bounded by $U$, we can have selling strategies with better performance. Thus, we may assume that the normalized market prices are in the range of $[1, U]$. Here we still assume that the highest market price is unknown; otherwise, the seller would exactly know the highest market price and will wait until the arrival of the buyer with the highest market price and then assign all products to this buyer. For this variant, El-Yaniv et al. [10] and Zhang et al. [16] gave $O(\log U)$-competitive algorithms for fractionally
solving products, and proved that the lower bound of the fractional case is $\Omega(\log U)$. Intuitively, when the number $L$ of products is sufficiently large, the atomic variant of the problem becomes equivalent to the fractional variant. In this part, we prove a lower bound on the competitive ratio for the atomic version and show that it is consistent with $\Omega(\log U)$, the bound for the fractional case, when $L$ is large enough. Furthermore, we give an online selling strategy for the atomic version, whose competitive ratio is almost tight w.r.t. the lower bound and is consistent with the upper bound $\log U$ of the fractional version when $L$ is sufficiently large.

**Theorem 6.** (Lower Bound) When products are atomic and the market price for a single product is in the range of $[1, U]$, the bounded one-way trading problem does not admit any online algorithms with competitive ratio less than $((U)^{1/L} - 1)L$, which is consistent with the lower bound of $\Omega(\log U)$ for the fractional version when $L$ is sufficiently large.

**Proof.** We use an adversary argument. Let $\hat{U} = (U)^{1/L}$. The adversary sends at most $L + 1$ buyers sequentially. For $i = 1, 2, \ldots, L$, the market price of the $i$-th buyer $u_i$ is $r_i = \hat{U}^N$, where $N_i$ is the total number of products sold to buyers before the arrival of buyer $u_i$, in particular, $N_1 = 0$ and $r_1 = 1$. As long as the seller sells at least one product to $u_i$, the adversary continues to send the next buyer $u_{i+1}$ with an increased price. Otherwise, if nothing is sold to $u_i$, the adversary stops sending more buyers.

Let $u_{i+1}$, $1 \leq l \leq L$, be the last buyer (who is unsatisfied) sent by the adversary. Let $n_i$, $1 \leq i \leq l$, be the number of products sold to buyer $u_i$, $N$ be the total number of sold products such that $N = N_{i+1} = \sum_{1 \leq i \leq l} n_i \leq L$, and $r_i = \hat{U}^N$. As the seller’s revenue is $\sum_{1 \leq i \leq l} n_ir_i$, the maximum revenue is $N - (l - 1) + \hat{U}^N - (l - 1) + \hat{U}^{N-2} + \cdots + \hat{U}^{N-1}$ when $n_1 = N - (l - 1)$, $n_2 = \cdots = n_l = 1$, which is bounded by $\hat{U}^0 + \hat{U}^1 + \cdots + \hat{U}^{N-1} = \frac{\hat{U}^N - 1}{(\hat{U} - 1)}$.

On the other hand, the optimal offline strategy would sell all $L$ products to $u_{i+1}$ at market price $r_{i+1} = \hat{U}^N$. Thus the competitive ratio is at least $\frac{\hat{U}^N L}{(\hat{U}^N - 1)(\hat{U} - 1)} \geq (\hat{U} - 1)L = ((U)^{1/L} - 1)L$. When $L$ is sufficiently large, $\lim_{L \to \infty}((U)^{1/L} - 1)L = \lim_{x \to 0}(x^r - 1)/x = \ln U$.

Now we give an online selling strategy to show the upper bound of the atomic variant, which is consistent with the upper bound $O(\log U)$ of the fractional variant when $L$ is large enough.

- **Partition Phase:**
  - If $L < \log U$, partition the price range $[1, U]$ into $L$ levels $[\hat{U}^0, \hat{U}^1)$, $[\hat{U}^1, \hat{U}^2)$, $\ldots$, $[\hat{U}^{L-1}, \hat{U}^L]$, and associate each level with a product, where $\hat{U} = (U)^{1/L}$.
  - If $L \geq \log U$, partition the price range $[1, U]$ into $\log U$ levels $[2^0, 2^1)$, $[2^1, 2^2)$, $\ldots$, $[2^{\log U-1}, U]$ and distribute $L$ products into these levels as uniform as possible.

- **Assignment Phase:** Sell all products in a level to the first buyer whose market price falls within that level.

**Theorem 7.** When the products are atomic and the market price for a single product is in the range of $[1, U]$, the bounded one-way trading problem admits an online algorithm with competitive ratio at most $((U)^{1/L} - 1)L$ if $L < \log U$, and $O(\log U)$ otherwise, which is consistent with the upper bound of the fractional version.

**Proof.** No matter the highest market price $r \leq U$ falls into any price level, we can ensure that all products associated with this price level in the partition will be sold with price no less than $r/\hat{U}$ (when $L < \log U$) or $r/2$ (when $L \geq \log U$). Consider the following two cases.

- When $L < \log U$, the competitive ratio of the algorithm is at most $((U)^{1/L} - 1)L$, i.e., in the worst case, at least 1 of the $L$ products is sold at a price at least $1/((U)^{1/L}$ of the maximum price of the highest level attained.
• When $L \geq \log U$, these $L$ atomic products are almost uniformly distributed into $[\log U]$ levels, there is at least $\left\lfloor \frac{L}{\log U} \right\rfloor$ products in each level. The maximum offline revenue is at most $L \cdot r$ while the revenue received from the above online strategy is at least $\left\lfloor \frac{L}{\log U} \right\rfloor \cdot \frac{r}{2}$. Thus, the upper bound of the competitive ratio in this case is at most $O(\log U)$.

4 One-Way Buying Problem

Note that the one-way buying problem is an online optimization problem. One easily sees that the offline counterpart can be fairly straightforward solved: since the buyer knows all the future prices, she simply waits for the lowest price and buys the whole unit at that price.

Analogously as in the one-way trading problem, we assume for the sequence of $n$ sellers $v_1, v_2, \ldots, v_n$ arriving online, the corresponding market prices are strictly decreasing, i.e. $p_1 > p_2 > \ldots > p_n \geq 0$. In practice, if there comes a higher price than the last price, the buyer simply purchase nothing. Therefore, $p^* = \min_i p_i = p_n$, and the highest possible market price is either $M$ if $M$ is given or $M = \varphi p_n$ if $\varphi$ is given. Note that we have an ideal case where $p_n = 0$, and the buyer simply purchases the remaining capacity at 0 cost.

The design of an optimal online algorithm for the one-way buying problem follows the same for the one-way trading problem. We distinguish two cases: $M$ is given or $\varphi$ is given.

4.1 Known maximum price $M$

Note that if the lowest price $m$ is also provided, then we may normalize $m$ to be arbitrarily close to 0, and thus we consider in this case the price range is $(0, M]$. We further normalize the price range to be the half-closed interval $(0, 1]$. Let $f(x) : (0, 1] \rightarrow \mathbb{R}^*$ be a density function representing the limit of fraction product to be purchased at price $x \in (0, 1]$. ($\mathbb{R}^*$ is the set of non-negative real numbers.) Then

$$\int_0^1 f(x)dx = 1,$$

and letting $p_0 = 1$, the purchase amount from seller $v_i$ at price $p_i$ is

$$\delta_i = \int_{p_i}^{p_{i-1}} f(x)dx, \text{ for } i = 1, 2, \ldots.$$

Let $g(x) = \frac{1}{x} f\left(\frac{1}{x}\right)$, then $g(x)$ maps from $[1, +\infty)$ to $\mathbb{R}^*$ and it is a density function in $[1, +\infty)$. That is,

$$\int_1^{+\infty} g(x)dx = 1; \quad (1)$$

and the purchase amount from seller $v_i$ at price $p_i$ is

$$\delta_i = \int_{\frac{1}{p_{i-1}}}^{1} g(x)dx, \text{ for } i = 1, 2, \ldots. \quad (2)$$

It follows that the purchase cost by Algorithm 5 is

$$p_1 \int_{1}^{\frac{1}{p_1}} g(x)dx + p_2 \int_{\frac{1}{p_1}}^{\frac{1}{p_2}} g(x)dx + \ldots + p_n \int_{\frac{1}{p_{n-1}}}^{\frac{1}{p_n}} g(x)dx + \int_{\frac{1}{p_n}}^{+\infty} g(x)dx$$

$$= 1 - (1 - p_1) \int_{1}^{\frac{1}{p_1}} g(x)dx - (1 - p_2) \int_{\frac{1}{p_1}}^{\frac{1}{p_2}} g(x)dx - \ldots - (1 - p_n) \int_{\frac{1}{p_{n-1}}}^{\frac{1}{p_n}} g(x)dx.$$
On the other hand, given the price sequence $p_1 > p_2 > \ldots > p_n$, an optimal offline algorithm purchases the whole unit of product at the lowest price $p_n$, incurring a total cost of $p_n$ only.

We next try to find a function $g(x)$, or equivalently $f(x)$, that minimizes the competitive ratio. When $n = 1$, the competitive ratio $\rho(p_1)$ is

$$\rho(p_1) = \frac{1 - (1 - p_1) \int_{\frac{1}{p_1}}^{\frac{1}{p_1}} g(x)dx}{p_1};$$

and thus $\lim_{p_1 \to 1} \rho(p_1) = 1$ and $\lim_{p_1 \to 0} \rho(p_1) \geq 1$, with

$$\rho'(p_1) = \frac{(1 - p_1)g(\frac{1}{p_1}) - p_1 + p_1 \int_{\frac{1}{p_1}}^{\frac{1}{p_1}} g(x)dx}{p_1^2}.$$

Setting $\rho'(p_1) = 0$, we have

$$g(x) = \frac{1}{(x - 1)^2}, \text{ and a primary function } G(x) = 1 - \frac{1}{x - 1}.$$

Therefore, we can set the density function to be

$$g(x) = \begin{cases} 0, & \text{if } 1 \leq x \leq 2; \\ \frac{1}{(x-1)^2}, & \text{if } x > 2, \end{cases} \quad (3)$$

which results in

$$\int_{1}^{x} g(t)dt = \begin{cases} 0, & \text{if } 1 \leq x \leq 2; \\ 1 - \frac{1}{x-1}, & \text{if } x > 2. \end{cases} \quad (4)$$

The competitive ratio $\rho(p_1)$ becomes

$$\rho(p_1) = \begin{cases} \frac{1}{p_1}, & \text{if } 1 \geq p_1 \geq \frac{1}{2}; \\ 2, & \text{if } p_1 < \frac{1}{2}. \end{cases} \quad (5)$$

When $n = 2$, the competitive ratio $\rho(p_1, p_2)$ is

$$\rho(p_1, p_2) = \frac{1 - (1 - p_1) \int_{\frac{1}{p_1}}^{\frac{1}{p_1}} g(x)dx - (1 - p_2) \int_{\frac{1}{p_2}}^{\frac{1}{p_2}} g(x)dx}{p_2};$$

and assuming $p_1 < \frac{1}{2}$, the same optimization process gives that

$$\rho(p_1, p_2) = \frac{1}{p_2} \left( 2p_1 - \frac{p_1 - p_2}{1 - p_1} \right). \quad (6)$$

In general, we assume the first price $p_1 < \frac{1}{2}$, then the purchase amount $\delta_i$ from seller $v_i$ at price $p_i$ is

$$\delta_i = \int_{\frac{1}{p_i}}^{\frac{1}{p_{i-1}}} g(x)dx = \frac{1}{1 - p_{i-1}} - \frac{1}{1 - p_i}, \text{ for } i = 1, 2, \ldots, n,$$

using the density function $g(x)$ in Eq. (3), and the achieved competitive ratio $\rho(p_1, p_2, \ldots, p_n)$ is

$$\rho(p_1, p_2, \ldots, p_n) = \frac{1}{p_n} \left( 2p_1 - \sum_{i=1}^{n-1} \frac{p_i - p_{i+1}}{1 - p_i} \right).$$

We therefore have proved the following theorem:

**Theorem 8.** When the maximum price $M$ is known, the one-way buying problem admits an optimal online algorithm with competitive ratio $\frac{1}{p_n} \left( 2p_1 - \sum_{i=1}^{n} \frac{p_i - p_{i+1}}{1 - p_i} \right)$, where $\frac{1}{2} > p_1 > p_2 > \ldots > p_n$ is the price sequence and the maximum price $M$ is normalized to 1. If the minimum price $p_n \geq \frac{1}{2}$, then the optimal online algorithm has competitive ratio $\frac{1}{p_n}$.  

13
4.2 Known price fluctuation ratio $\varphi$

With known $\varphi$, given the current minimum price $p_i$ we have $p_1 \leq M \leq p_i$, and thus we consider in this case the price range is $[p_1/\varphi, p_i\varphi]$. The difference from the case of known maximum price is that, here the maximum possible price changes whenever a new market price is revealed. Let $f(x): [p_1/\varphi, p_i\varphi] \rightarrow \mathbb{R}^*$ be a density function. Then

$$\int_{p_1/\varphi}^{p_i\varphi} f(x)dx = 1,$$

and letting $p_0 = p_1\varphi$, the purchase amount from seller $v_i$ at price $p_i$ is

$$\delta_i = \int_{p_i}^{p_{i-1}} f(x)dx, \text{ for } i = 1, 2, \ldots.$$

The purchase cost therefore is

$$p_1 \int_{p_1}^{p_i\varphi} f(x)dx + p_2 \int_{p_2}^{p_1\varphi} f(x)dx + \ldots + p_n \int_{p_{n-1}}^{p_i\varphi} f(x)dx + p_n\varphi \int_{p_1/\varphi}^{p_{n-1}} f(x)dx.$$

On the other hand, given the price sequence $p_1 > p_2 > \ldots > p_n$, an optimal offline algorithm purchases the whole unit of product at the lowest price $p_n$, incurring a total cost of $p_n$ only.

When $n = 1$, the competitive ratio $\rho(p_1)$ is

$$\rho(p_1) = \frac{p_1 \int_{p_1}^{p_i\varphi} f(x)dx + p_1\varphi \int_{p_1/\varphi}^{p_i\varphi} f(x)dx}{p_1} = 1 + (\varphi - 1) \int_{p_1/\varphi}^{p_1} f(x)dx;$$

and

$$\rho'(p_1) = (\varphi - 1) (f(p_1) - f(p_1/\varphi)/\varphi).$$

Setting $\rho'(p_1) = 0$, from Eq. (7) we have

$$f(x) = \frac{1}{2\ln \varphi} \cdot \frac{1}{x}, \text{ and } \delta_1 = \int_{p_1}^{p_i\varphi} f(x)dx = \frac{1}{2\ln \varphi} (\ln p_1 + \ln \varphi - \ln p_1) = \frac{1}{2}.$$

Therefore, the competitive ratio $\rho(p_1)$ becomes

$$\rho(p_1) = 1 + (\varphi - 1) \frac{1}{2} = \frac{\varphi + 1}{2}. \quad (8)$$

When $n = 2$, the competitive ratio $\rho(p_1, p_2)$ is

$$\rho(p_1, p_2) = \frac{p_1 \delta_1 + p_2 \int_{p_2}^{p_1\varphi} f(x)dx + p_2\varphi \int_{p_1/\varphi}^{p_2\varphi} f(x)dx}{p_2} = \frac{p_1}{2p_2} + \frac{1}{2} + (\varphi - 1) \int_{p_1/\varphi}^{p_2} f(x)dx;$$

and

$$\frac{\partial}{\partial p_2} \rho(p_1, p_2) = -\frac{p_1}{2p_2^2} + (\varphi - 1)f(p_2).$$

Setting $\frac{\partial}{\partial p_2} \rho(p_1, p_2) = 0$, we have

$$f(x) = \frac{p_1}{2(\varphi - 1)x^2}, \text{ and } \delta_2 = \int_{p_2}^{p_1} f(x)dx = \frac{p_1}{2(\varphi - 1)} \left( \frac{1}{p_2} - \frac{1}{p_1} \right).$$

14
In general, for \(i \geq 2\), the purchase amount \(\delta_i\) from seller \(v_i\) at price \(p_i\) is

\[
\delta_i = \int_{p_i}^{p_{i-1}} f(x) dx = \frac{p_1}{2(\varphi - 1)} \left( \frac{1}{p_i} - \frac{1}{p_{i-1}} \right),
\]

and the achieved competitive ratio \(\rho(p_1, p_2, \ldots, p_n)\) is

\[
\rho(p_1, p_2, \ldots, p_n) = \frac{1}{2(\varphi - 1)p_n} \left( (p_n\varphi^2 - p_1) + p_1 \sum_{i=2}^{n} \left( 1 - \frac{p_i}{p_{i-1}} \right) \right).
\]

We therefore have proved the following theorem:

**Theorem 9.** When the fluctuation ratio \(\varphi\) is known, the one-way buying problem admits an optimal online algorithm with competitive ratio

\[
\frac{1}{2(\varphi - 1)p_n} \left( (p_n\varphi^2 - p_1) + p_1 \sum_{i=2}^{n} \left( 1 - \frac{p_i}{p_{i-1}} \right) \right),
\]

where \(p_1 > p_2 > \ldots > p_n \geq p_1/\varphi\) is the price sequence.

## 5 Conclusions

There are many real applications where the market price fluctuates and cannot be controlled by the seller. It is a problem of practical interest to find a good revenue-maximizing (or profit-maximizing) selling strategy for the seller in such a situation. This paper has made an attempt towards this direction. However, the strategy prescribed in this paper may not be too practical in the sense that, for example, products are not sold when the market price decreases. The reality is that, in practice, the seller may have a fixed time-frame to sell and cannot wait forever for the buyer with the highest price to arrive, and price movements from one moment to the next may not be drastic or arbitrary. Additional assumptions and/or constraints to the unbounded one-way trading problem to reflect such practical realities will be studied in our next attempt and hopefully could lead to more practical selling strategies.

## 6 Acknowledgements

The authors thank Dr. Bethany M.Y. Chan and Prof. Marek Chrobak for many valuable comments and their efforts in making this paper more readable. ## References

Appendix

**Lemma 5.** For any integer \( h \geq 1 \) and \( k \geq 1 \), there exist a constant \( c > 1 \), such that

\[
\frac{e \cdot q_{h,0}(b_h + k - 1)}{q_{h,0}(b_h + k)} \geq c
\]

**Proof.** Based on the logarithmic characteristic of \( q_{h,0}(x) \), \( \frac{q_{h,0}(b_h + k - 1)}{q_{h,0}(b_h + k)} \) achieves the lowest value when \( k = 1 \). Thus, it is sufficient to prove the following inequality for any integer \( h \geq 1 \).

\[
\frac{e \cdot q_{h,0}(b_h)}{q_{h,0}(b_h + 1)} \geq c > 1
\]

We prove Inequality (9) by induction on \( h \).

**Basis step:** \( h = 1 \). As \( b_h = e \),

\[
\frac{e \cdot q_{1,0}(b_1)}{q_{1,0}(b_1 + 1)} = \frac{e \cdot b_1 \cdot \ln b_1}{(b_1 + 1) \cdot \ln(b_1 + 1)} \approx 1.513 > 1
\]

**Induction step:** Assume Inequality (9) is true for \( h \),

\[
\frac{e \cdot q_{h,0}(b_h)}{q_{h,0}(b_h + 1)} = \frac{e \cdot b_h \cdot \ln b_h \cdot \ldots \cdot \ln^{(h)} b_h}{(b_h + 1) \cdot \ln(b_h + 1) \cdot \ldots \cdot \ln^{(h)}(b_h + 1)}
\]

\[
= \frac{e \cdot b_h}{b_h + 1} \prod_{h' = 1}^{h} \frac{\ln^{(h')} b_h}{\ln^{(h')} (b_h + 1)} \geq c > 1 \tag{9}
\]

Then for \( h + 1 \),

\[
\frac{e \cdot q_{h+1,0}(b_{h+1})}{q_{h+1,0}(b_{h+1} + 1)} = \frac{e \cdot b_{h+1} \cdot \ln b_{h+1} \cdot \ldots \cdot \ln^{(h+1)} b_{h+1}}{(b_{h+1} + 1) \cdot \ln(b_{h+1} + 1) \cdot \ldots \cdot \ln^{(h+1)}(b_{h+1} + 1)}
\]

\[
= \frac{e \cdot b_{h+1}}{b_{h+1} + 1} \prod_{h' = 1}^{h+1} \frac{\ln^{(h')} b_{h+1}}{\ln^{(h')} (b_{h+1} + 1)} \geq c > 1 \tag{10}
\]

We shall prove that \( \frac{e \cdot b_{h+1}}{b_{h+1} + 1} \prod_{h' = 1}^{h+1} \frac{\ln^{(h')} b_{h+1}}{\ln^{(h')} (b_{h+1} + 1)} \) as given in Equation (10) is larger than \( \frac{e \cdot b_h}{b_h + 1} \prod_{h' = 1}^{h} \frac{\ln^{(h')} b_h}{\ln^{(h')} (b_h + 1)} \) as given in Equation (9) term by term. Since \( \ln b_{h+1} = b_h \), we have \( \ln(b_{h+1} + 1) < b_h + 1 \). Thus, for any \( 2 \leq h' \leq h + 1 \),

\[
\frac{\ln^{(h')} b_{h+1}}{\ln^{(h')} (b_{h+1} + 1)} > \frac{\ln^{(h'-1)} b_h}{\ln^{(h'-1)} (b_h + 1)}
\]

As for the first few terms, because \( \ln b_{h+1} = b_h \) and \( \ln(b_{h+1} + 1) = b_h + \delta \), where \( \delta \ll 1 \), we have

\[
\frac{b_{h+1} \cdot \ln b_{h+1}}{(b_{h+1} + 1) \cdot \ln(b_{h+1} + 1)} \geq \frac{b_h}{b_h + 1}
\]

Thus, we have shown that

\[
\frac{e \cdot q_{h,0}(b_h + k)}{q_{h,0}(b_h + k + 1)} \geq c > 1.
\]
