Abstract — The cadmium chloride activation treatment of cadmium telluride solar cells is essential for producing high efficiency devices. The treatment has many effects but the most significant is the complete removal of stacking faults in the cadmium telluride grains and the diffusion of Chlorine along the grain boundaries of the device. Chlorine decorates all cadmium telluride and cadmium sulphide grain boundaries and also builds up along the CdTe/CdS junction. This paper reveals that by annealing devices to temperatures of 400ºC to 480 ºC for times ranging from 30 to 600 seconds in moderate vacuum results in the reappearance of stacking faults and the removal of Choline from the grain boundaries. STEM analysis confirms the reappearance of the stacking faults and SIMS and EDX confirm the removal of chlorine from the grain boundaries. This directly corresponds to a lowering in cell efficiency. The study provides further evidence that CdCl₂ diffusion and certain microstructural defects directly affect the performance of cadmium telluride photovoltaic devices.

Index Terms — CdTe, PV, CdCl₂, TEM, EDX, SIMS

I. INTRODUCTION

Cadmium telluride is an important photovoltaic material used as an absorber due to its excellent properties for photon conversion currently exceeding an annual production of 2 GW. Laboratory cell efficiencies have reached 21.5% and commercial module efficiencies of 17% have been reported [1]. An essential step in the production of efficient thin film cadmium telluride solar cells is an activation process that involves treating the cadmium telluride layer with cadmium chloride at a temperature of ~400ºC [2,3]. The as deposited material is polycrystalline and although the grain size depends on the method of deposition, all the methods produce material with high densities of planar defects such as stacking faults and twin boundaries [4]. Recent work using Density Functional Theory (DFT) has shown that certain types of stacking fault are high energy hole traps [5].

The cadmium chloride passivation causes the cadmium telluride grains to recrystallize. During recrystallization the planar stacking faults are completely eradicated. Twin boundaries often remain after the recrystallization, but work using DFT modeling shows these are electrically benign and do not act as hole traps[5]. Although over-treatment using higher temperatures or longer cadmium chloride treatment times continues to improve the morphology of the films, however chlorine builds up at the CdS/CdTe interface damaging the junction [5]. We have used a post-annealing process in an attempt to remove chlorine from the device. We have annealed cadmium telluride devices from 400ºC to 480ºC, causing a reduction in efficiency. Microstructural and elemental characterization of these annealed devices has been carried out to determine the cause of the degradation of the cells. By using a second cadmium chloride treatment, identical to the first, which restored the cell efficiency. The microstructure and performance of these re-passivated devices has also been characterized.

II. EXPERIMENTAL

A. Cadmium Telluride Deposition and the Cadmium Chloride Activation Treatment

The thin film cadmium telluride cells were deposited in a superstrate configuration using close-spaced sublimation (CSS) on NSG-Pilkington TEC10 fluorine doped tin oxide (FTO) coated on 3 mm soda lime glass. A thin layer of cadmium sulphide was deposited onto a plasma cleaned transparent conducting oxide [7]. This was followed by the CSS deposition of the cadmium telluride film. The devices then underwent a previously optimized post deposition cadmium chloride activation treatment [3]. The devices then underwent a previously optimized post deposition cadmium chloride activation treatment [3]. This was followed by a copper doping process using copper chloride [3,8]. The efficiency of this cell was measured to be above 12%. The cell efficiency before the cadmium chloride treatment was measured to be <1%.

B. Post-Treatment Anneal

The optimized devices were then post-annealed in a 40 mTorr Argon atmosphere. This post-annealing process was performed in the absence of a CdCl₂ vapor pressure. The substrate temperatures used for the post-annealing processes were 400ºC, 440ºC and 480ºC. The times used for the post-annealing process were also varied from 35 to 600 seconds. The sample treated at 480ºC for 600 seconds underwent a second cadmium chloride treatment after the post-annealing treatment.
C. Characterization Methods

Samples for Transmission Electron Microscopy (TEM) were prepared by Focused Ion Beam (FIB) milling using a dual beam FEI Nova 600 Nanolab. A standard in situ lift out method was used to prepare cross-sectional samples through the coating into the glass substrate. An electron beam assisted platinum (e-Pt) over-layer was deposited followed by an ion assisted layer to define the surface and homogenize the final thinning of the samples down to 100 nm. TEM analysis was carried out using a Tecnai F20 operating at 200 kV to investigate the detailed microstructures of the cell cross sections. The system was equipped with an Oxford instruments X-max N80 TLE SDD energy-dispersive X-ray spectroscopy (EDX) detector and this was used in STEM mode to collect elemental distribution maps. These maps were collected in a single frame using a long dwell time, as well as a small condenser aperture (70 microns) to minimize drift and beam spread during data collection. A Cameca IMS 3F was used for secondary ion mass spectrometry (SIMS) depth profiling. The analysis was performed using Cs+ primary ion bombardment at 10 keV with a current of 1 μA with a spot size of 60 μm and negative secondary ion detection to optimise the sensitivity to chlorine.

III. RESULTS

A. As-Deposited and Cadmium Chloride Treated Cells

Figure 1a shows a high resolution image of an untreated cadmium telluride grain with a high density of planar defects. Lower resolution studies show that all the defects terminate at a grain boundary. Figure 1b shows another high resolution image from a cadmium chloride treated cadmium telluride grain with a perfect lattice. This is typical for treated and untreated grains. After the cadmium chloride treatment large areas of the cadmium telluride grains appear defect free with the exception of the regular appearance of twin boundaries.

The removal of planar defects correlates with the diffusion of chlorine into the device. Figure 2 shows a dynamic SIMS depth profile using caesium ions, carried out on the cadmium chloride treated sample. The chlorine concentration in the cadmium telluride was quantified using reference standards. In the bulk cadmium telluride, the chlorine concentration is constant at 0.07 at% increasing slightly to 0.08 at%. However, at the cadmium sulphide interface, the chlorine concentration peaks at 0.7 at%. This concentration is an order of magnitude higher than that measured in the bulk cadmium telluride. The sulphur concentration-depth profile shows that the sulphur diffuses from the cadmium sulphide into the cadmium telluride layer.

The STEM/EDX elemental maps shown in figure 3 are from a cadmium chloride passivated device. The cross-sectional image shows clear chlorine segregation along the cadmium telluride and cadmium sulphide grain boundaries as well as sulphur diffusion into the cadmium telluride film; however the chlorine does not penetrate into the FTO layer. Twin boundaries are clearly visible in the cadmium telluride grains but there is no trace of stacking faults.
B. The Effect of the Post-Annealing Temperature on Passivated Cells

Passivated cadmium telluride devices were post-annealed at 3 different temperatures, 400ºC, 440ºC and 480ºC for 35 seconds. The post-annealing treatment of the cadmium telluride devices caused a surprising reduction in efficiency. The treated devices had an average efficiency of 12% after the cadmium chloride treatment. Annealing at 400ºC for 35 seconds caused a reduction in cell efficiency as shown in figure 4. Increasing the temperature to 480ºC for 35 seconds caused a dramatic decrease in efficiency to 3%.

Cross-sections of the post-annealed cadmium telluride cells were then analyzed to investigate if any changes in microstructure had occurred to explain the observed degradation in efficiency. Figure 5 shows a bright field STEM image of a cross section of a cadmium telluride cell which has been activated using cadmium chloride and then undergone a post-annal at 400ºC for 35 seconds without cadmium chloride. This treatment caused a moderate reduction in efficiency from 12% to 10.88% as shown in figure 4. The remarkable image shown in figure 5 clearly shows the presence of stacking faults in a grain located near to the surface. The re-emergence of stacking faults in the cadmium telluride layer correlates directly with the reduction in efficiency.

Figure 6 shows the EDX chlorine maps collected from a passivated cell, then post annealed at 400ºC and then 480ºC. The device annealed at 400ºC shows that chlorine is still present in the device and is located in the grain boundaries and at the cadmium sulphide interface. However the chlorine map is much less intense than that from the un-annealed cell. The loss of intensity corresponds to a loss of chlorine from the device. This trend is accentuated as the post-annealing temperature is increased to 480ºC as shown in figure 6b. This image shows no evidence for the presence of chlorine in the cell within the sensitivity limits of EDX.
Fig. 7. SIMS depth profiles of chlorine 35 showing the variation in concentration at different post-annealing temperatures. The concentration of chlorine reduces sharply with increasing temperature.

Elemental mapping with EDX has a sensitivity typically in the range ~0.1at% to 1at%, so dynamic SIMS was used to confirm the removal of chlorine in the post-annealed devices. Figure 7 shows the chlorine concentration with depth through a number of devices including the as-deposited cell as a reference. This depth profile shows that there is a residual chlorine concentration in the as-deposited and untreated material. As expected, the chlorine concentration in the cells confirms its sharp reduction with increasing post annealing temperature.

The post annealing process is clearly driving the chlorine out of the device. The removal of chlorine from the grain boundaries appears to cause the re-emergence of high densities of stacking faults in the cadmium telluride grains which in turn correlates with the reduction in efficiency. The chlorine concentration from the three post annealed cells is lowest in the cell annealed at 480°C.

Fig. 8. STEM/EDX sulphur elemental maps for a) As deposited b) cadmium chloride treated devices showing the diffusion of sulphur from the cadmium sulphide into the cadmium telluride film. The diffusion occurs within the grains and is not concentrated along grain boundaries.

Figure 8a maps the sulphur elemental from an as-deposited device and figure 10b is the sulphur elemental map following the cadmium chloride treatment. Comparison of these images shows that sulphur migration clearly occurs from the cadmium sulphide layer into the cadmium telluride film. The diffusion occurs within the grains and is not concentrated along grain boundaries.

Fig. 9. SIMS depth profiles of sulphur 34 showing the variation in concentration at different annealing temperatures

Dynamic SIMS depth profiling analyses were carried out to observe the changes in sulphur concentration in the cadmium telluride following post-annealing at 400°C and 480°C. These sulphur depth profiles are shown in figure 9 and can be compared with the as-deposited device and the high efficiency cell following cadmium chloride passivation but without post-annealing as references.

Fig. 10. STEM/EDX of the treated cell post-annealed at 400°C for 120 seconds. High densities of stacking faults have re-emerged in a number of near surface grains.
Figure 9 shows an increase in sulphur concentration in the cadmium telluride layer after the cadmium telluride treatment as well as a general broadening of the cadmium sulphide. However, the J-V data in figure 4 indicates severe efficiency degradation. Clearly, the loss of efficiency is linked closely with the removal of chlorine rather than sulphur diffusion from the cadmium sulphide layer.

The observation that chlorine is removed by the post-annealing process is supported by the EDX/STEM maps shown in figure 10 which show the distribution of sulphur and chlorine in the cadmium telluride following a post annealing treatment at 400°C for 120 seconds. The sulphur distribution is unaffected but chlorine is no longer detected even at the grain boundaries. Figure 10 also shows a BF-STEM image revealing the reappearance of stacking faults. There is a clear correlation between the removal of chlorine, the reappearance of high densities of stacking faults and the reduction in cell efficiency.

C. The Effect of the Post-Annealing Time on Activated Cells

The efficiency of devices post-annealed for longer periods of time was also investigated. Figure 11 shows the J-V curves of a series of cadmium telluride cells.

![Fig. 11. J-V curves of a treated and untreated cadmium telluride cells and then post-annealed at 480°C for 30, 120 and 600 seconds.](image)

The low efficiency as-deposited cell is without activation using cadmium chloride. The high efficiency device is the cadmium chloride treated device without further post-annealing. The remaining three J-V curves correspond to activated devices that have been post annealed at 480°C at increasing times of 30 seconds, 120 seconds and 600 seconds. The cell efficiency degrades rapidly and continues to degrade with increasing treatment time corresponding to the reduction in chlorine concentration.

D. The Effect of a Second Cadmium Chloride Treatment on Post-Annealed Cells

Figure 12 shows the J-V data for untreated and treated cadmium telluride cells, compared with a post-annealed cell (480°C for 600 seconds) exhibiting substantial performance loss and that exact same post-annealed cell with a 2nd cadmium chloride passivation treatment.

Fig. 12. J-V curves for cadmium telluride cells which have undergone post-annealing treatments and a second treatment with cadmium chloride.

The J-V data shows that post-annealing the cell for 600 seconds at 480°C dramatically degrades cell efficiency but still out performs the untreated cadmium telluride material. Then as the post-annealed cell was re-passivated with a second standard cadmium chloride treatment, the efficiency of the cell was restored to its original efficiency.

![Fig. 13. EDX maps of sulphur and chlorine from a post-annealed cell after a second cadmium chloride treatment.](image)

Figure 13 shows EDX maps of sulphur and chlorine from a post-annealed cell (for 600 seconds at 480°C) which then underwent a second cadmium chloride treatment. It shows that chlorine reappears and decorates the grain boundaries of the cadmium telluride and the cadmium sulphide layers. The stacking faults in the cadmium telluride grains are once again removed. The efficiency of this device was restored as shown in the J-V data in figure 12.
The second cadmium chloride treatment fully restores the functionality of the cells by reintroducing chlorine to the grain boundaries. In-turn this removes the stacking faults which prevent the free movement of holes [4]. This is interesting because it indicates that a process could be devised to control and optimize the location and concentration of chlorine in the devices.

IV. CONCLUSIONS

The cadmium chloride treatment is a vital process for high efficiency thin film cadmium telluride devices. The effects of this treatment are complex as are the mechanisms at work that allow the devices to operate with high conversion efficiency. We have shown previously that the cadmium chloride process completely removes high densities of stacking faults present in the as deposited material.

High densities of stacking faults have been observed in cadmium telluride layers deposited by a number of deposition techniques including close spaced sublimation, electro-deposition and magnetron sputtering. Chlorine diffuses through the cadmium telluride grain boundaries to the cadmium telluride/cadmium sulphide junction and into the cadmium sulphide layer. The presence of chlorine in the grain boundaries appears to be necessary to remove the stacking faults. However, excess chlorine at the junction is harmful to the performance of the devices.

In this study we have shown that a post-annealing treatment can be used to remove chlorine from the device. Surprisingly, the high densities of stacking faults re-appear and this corresponds to a decrease in cell efficiency. The re-appearance of the defects corresponds to the removal of chlorine from the grain boundaries. The post-annealing treatment increases the diffusion of sulphur into the cadmium telluride layer.

If these post-annealed cells are then subject to a second cadmium chloride treatment, the stacking faults are again completely removed, and the cell efficiency is restored, chlorine is once more detected at the cadmium telluride and cadmium sulphide grain boundaries and at the cadmium telluride/cadmium sulphide junction. This provides further evidence for the link between the presence of stacking faults, chlorine, and cell efficiency.

In addition to assisting our understanding of the mechanisms at work, these experiments may provide the groundwork for the optimization of a potentially useful post-annealing process which may further improve the grain microstructure but may also help to control and optimize the concentration of chlorine at the cadmium telluride/cadmium sulphide junction.
