Abstract

To advance understanding of hydroclimatological processes, this paper links spatiotemporal variability in gridded European precipitation and large-scale mean sea level pressure (MSLP) time-series (1957-2002) using monthly concurrent correlation. Strong negative (positive) correlation near Iceland and (the Azores) is apparent for precipitation in northwest Europe, confirming a positive North Atlantic Oscillation (NAO) association. An opposing pattern is found for southwest Europe, and Mediterranean in winter. In the lee of mountains, MSLP correlation is lower reflecting reduced influence of westerlies on precipitation generation. Importantly, European precipitation is shown to be controlled by physically interpretable climate patterns that change in extent and position from month-to-month. In spring, MSLP-precipitation correlation patterns move and shrink, reaching a minimum in summer, before expanding in the autumn, and forming an NAO-like dipole in winter. These space-time shifts in correlation regions explain why fixed-point NAO indices have limited ability to resolve precipitation from some European location and seasons.

Keywords: Hydroclimatology; Large-scale climate; Precipitation; Europe; ERA-40; NAO; Correlation analysis
1. Introduction

European precipitation receipt is dynamic seasonally and spatially (Zveryaev, 2004). This variability in precipitation can lead to floods or droughts, which have major socio-economic impacts over Europe (Lorenzo et al., 2008, Zveryaev and Allan, 2010). Agriculture, water resources management and other sectors are reliant on timely and sufficient precipitation supply, with extreme variability potentially causing water shortages and crop failures, or flood inundation in both urban and rural areas. Identification of hydroclimatological relationships between large-scale climatic circulation and precipitation occurrence helps in understanding the climate drivers of precipitation, which may lead to an improvement in skill of climate prediction (Zveryaev and Allan, 2010). With skilful climate prediction, it would be possible to anticipate precipitation and associated hydrological anomalies, which would help mitigate negative impacts and provide societal benefits.

The average pole-to-equator temperature gradient in the Northern Hemisphere is larger in winter than summer. According to the thermal wind relationship, a horizontal temperature gradient causes vertical zonal (west-east) wind shear resulting in a region of maximum zonal wind near the tropopause that is called the ‘jet stream’ (Holton, 1992). As the largest temperature gradient occurs in winter, jet streams are also strongest in winter. Over the North Atlantic, they occur just east of North America between 30°N and 35°N in winter and between 40°N and 45°N in summer. Weather systems develop typically in these jet stream regions and travel eastward along storm tracks towards Europe (Holton, 1992). In winter, synoptic weather systems pick up moisture from the North Atlantic and transport the warm moist air and precipitation over Europe.
on the western edge of the European continent (e.g. British Isles and Scandinavia) are most affected by these weather systems, while inland areas (e.g. Central Europe) are less affected by systems from the Atlantic Ocean (Wibig, 1999) and so experience a continental climate (Berg et al., 2009). In turn, high winter precipitation is found over Western Europe which is intensified by coastal mountains that force the moisture-laden Atlantic air to rise (i.e. orographic enhancement). In contrast, low winter precipitation occurs over Eastern Europe and Russia. Note that high winter precipitation variability tends to occur in regions of maximum precipitation, and low winter precipitation variability occurs in regions of minimum precipitation (Zveryaev, 2004). In summer (warm-season), local-scale processes are thought to play a key role in precipitation receipt, in part because European precipitation has a significant statistical relationship with European land surface evaporation (Zveryaev and Allan, 2010). Convective precipitation events are more prevalent in summer (Berg et al., 2009), with precipitation generally being larger over the central continental parts of Europe and lower near the continental extremities (Zveryaev, 2004). Interestingly summer evaporation from the North Atlantic is not found to relate to European precipitation, which is in stark contrast to the winter (Zveryaev and Allan, 2010). This suggests that the strong winter jet stream and associated synoptic-scale weather systems subside in summer (because of the weaker pole-to-equator temperature gradient), thus limiting this mode of conveyance of North Atlantic moisture and precipitation over Europe.

Indices that describe the state of the large-scale atmospheric circulation have been used frequently to quantify the connection between the large-scale atmosphere and precipitation (as reviewed below). The North Atlantic Oscillation (NAO), which refers
to the redistribution of atmospheric mass between the subtropical Atlantic and the Arctic, is the leading mode of atmospheric variability in the North Atlantic basin (Marshall et al., 2001). Changes in the NAO phase, as characterised by the NAO index (NAOI), are associated with variations in the frequency and strength of the surface westerly winds over Europe, influencing the transport and convergence of atmospheric moisture and in turn, regional precipitation patterns (Marshall et al., 2001). Winter Scandinavian and Baltic precipitation increases with westerly winds, and hence for a positive NAOI (Hurrell, 1995, Uvo, 2003, Jaagus et al., 2010). Precipitation in northern Britain has also shown a significant positive correlation with the NAOI in winter (Wilby et al., 1997, Fowler and Kilsby, 2002). Conversely, over the Iberian Peninsula, winter precipitation is negatively correlated with the NAOI (Hurrell, 1995, Lorenzo et al., 2008). In the European Alps, precipitation has shown little relation with the NAOI, possibly due to the complex terrain (Bartolini et al., 2009). In general, the NAOI has a stronger link with winter precipitation in coastal European countries, such as Greece, Spain, parts of Scandinavia and the UK (Bouwer et al., 2008), and a weaker link with winter precipitation in European regions more remote from the Atlantic Ocean (Wibig, 1999).

As the atmosphere is most dynamically active during winter, most previous analyses have focused on the winter season (Folland et al., 2009) and the NAOI, with far less attention given to investigating summer (Zveryaev, 2004, Zveryaev and Allan, 2010). In summer, there is a leading pattern of climatic variability known as the summer North Atlantic Oscillation (SNAO) pattern. The SNAO is spatially smaller and located further north than the well-known NAO definition. In a positive SNAO phase, high pressure is
present over Northwest Europe and low pressure is present over Greenland and the Mediterranean (Zveryaev, 2004). Under this circulation pattern, warm and dry conditions occur over Northwest Europe (e.g. British Isles) and cool wet conditions occur over southern Europe and the Mediterranean. As such, precipitation has significant negative correlation with the SNAO in Northwest Europe, and significant positive correlation with the SNAO in southern Europe (Folland et al., 2009). Historical observations have shown there to be significant statistical relationships between the large-scale circulation and precipitation, but only for some European locations and seasons. Few studies have investigated systematically the important large-scale atmospheric influence on summer precipitation variation by month at the continental scale.

The availability of gridded observed precipitation and gridded atmospheric re-analysis mean sea-level pressure (MSLP) data has made it possible to undertake a consistent and systematic spatiotemporal analysis of the large-scale climatic control on European precipitation. The aim of this paper is to understand the spatiotemporal variability of European precipitation by quantifying the changing connections with large-scale MSLP fields. This will reveal where and when the hydroclimatological links are strongest, and give insight into the different precipitation-generating atmospheric circulations across Europe. This paper is structured as follows: section 2 contains the data and methodology; sections 3, 4 and 5 present and discuss the results; and section 6 draws conclusions on the results found.
2. Data and Methodology

Two gridded datasets were used: (1) daily observed gauge-based precipitation (E-OBS dataset) produced by the ENSEMBLES project (Hewitt and Griggs, 2004; Haylock et al., 2008) at a 0.5°×0.5° resolution across central and western Europe (36.25°N–74.25°N and 10.25°W–24.75°E) [North African precipitation time series in the study domain were not used as some series were incomplete]; and (2) daily MSLP from the ERA-40 re-analysis dataset (Uppala et al., 2005) on a 2.5°×2.5° grid over half of the Northern Hemisphere (0°N–90°N and 90°W–90°E). MSLP is used as an explanatory variable of European precipitation, as MSLP is collocated with vertical velocity in the mid-troposphere and, therefore, indicative of cyclonic development and precipitation. Monthly precipitation and MSLP time series were derived for the common data period of September 1957 – August 2002. Monthly data were used in our analysis because daily data have been found to be too noisy to detect the fundamental climatic controls on precipitation (Lavers et al., 2010). Two versions of the NAOI were used to act as a benchmark against which to compare the links with gridded MSLP: (1) a fixed station-based NAOI from the University of East Anglia (UEA) Climatic Research Unit (CRU) ([http://www.cru.uea.ac.uk/cru/data/nao/nao.dat](http://www.cru.uea.ac.uk/cru/data/nao/nao.dat)), and (2) an Empirical Orthogonal Function (EOF) based NAOI from the Climate Analysis Section at the National Center for Atmospheric Research (NCAR) ([http://www.cgd.ucar.edu/cas/jhurrell/indices.data.html](http://www.cgd.ucar.edu/cas/jhurrell/indices.data.html)).

The univariate normality of the MSLP and precipitation time series was tested using the Shapiro-Wilk test (significance level $\alpha = 0.05$) as it is one of the most powerful tests for detecting non-normality (Helsel and Hirsch, 1992). Results suggested that some time
series were not normally distributed; therefore, the non-parametric Spearman Rank

Correlation

analysis was carried out between MSLP at each grid in the atmospheric domain and
each grid of observed precipitation by month (n = 45) to assess the detailed spatial
variation of MSLP control on European monthly precipitation.

Monthly field significance of the observed MSLP correlation fields (at each
precipitation grid) was examined using Monte Carlo simulations to determine whether
the observed significant MSLP correlation areas were greater than those expected by

Monte Carlo simulations. For each simulation, a series of 45 values (i.e. same as the length of

the empirical distribution of the precipitation time series, and then correlated with the

MSLP time series at each of the 2701 grid points in the MSLP field. The number of

MSLP grid points with significant ranked correlation at the 0.05 level was recorded. An

observed correlation pattern is considered field significant at the 0.05 level, if the area

of observed significant correlation is larger than that expected by chance, as given by the 95% percentile of the empirical probability distribution constructed from the 200

Monte Carlo simulations. Correlation patterns that are field significant are to be

considered as possible centres of atmospheric circulation related to precipitation.
The Mann-Kendall trend test (significance level $\alpha = 0.05$) was used to determine if trends were present in the monthly MSLP and precipitation time series (e.g. Helsel and Hirsch, 1992) and to assess if spurious MSLP-precipitation correlations could result as a result of any trends. For each month, precipitation time series that had increasing or decreasing linear trends (at $\alpha = 0.05$) underwent a bootstrap procedure to determine if the presence of the trend affected the significance of the correlations with MSLP (following Efron and Tibshirani (1998)). Note that the bootstrapping process destroys any temporal trends in both the MSLP and precipitation time series. The following bootstrap process was repeated $B=1000$ times. For each bootstrap sample $B$, precipitation (at a particular grid) and MSLP (at all 2701 grid points) time series of the same size as the observed series ($n=45$) were re-sampled with replacement keeping the concurrent pairs. At each MSLP grid cell, Spearman’s correlation $\rho$ between re-sampled precipitation (at a particular grid) and MSLP was computed, providing an empirical bootstrap distribution of 1000 $\rho$ values for each MSLP grid point. If 95\% of the constructed empirical bootstrap distribution has a correlation $\rho > 0$ or $\rho < 0$, the trend has no impact on the significance of the correlation at the 0.05 significance level. This significance threshold was used for all MSLP grid points for the relevant precipitation grids. Using this approach, it was possible to assess if the correlations obtained for the observed time series were significant despite a possible presence of trends in these time series.

A spatially nested research design is adopted to facilitate clear presentation of results for different spatial scales and locations. Six precipitation grid locations were chosen \textit{a priori} to test the hypothesis that precipitation dynamics are different across Europe.
These locations are: (1) western Scotland (57.25°N 5.25°W), (2) Norway (65.25°N 13.75°E), (3) southern Spain (37.75°N 3.75°W), (4) central France (47.25°N 3.25°E), (5) Czech Republic (49.75°N 15.25°E), and (6) the Balkans (42.75°N 20.25°E).

Scaling-up from these individual grids, results are presented for all precipitation grids across the British Isles and, at a larger scale still, for all precipitation grids across Europe. The latter provides a novel wider perspective on connections between MSLP and precipitation in Europe.

3. Precipitation variability, field significance testing and trend analysis

3.1. European precipitation variability and the CRU NAOI

Figure 1 shows the standardised January precipitation anomalies for six locations across Europe with the CRU NAOI [NAOI-precipitation correlation analyses are the focus of Section 5]. In general, precipitation anomalies are in phase with the NAOI in northern Europe (western Scotland and Norway; Figure 1a and 1b respectively) and out of phase with the NAOI in southern Europe (southern Spain and the Balkans; Figure 1c and 1f respectively), which is consistent with the regional precipitation linkages with the large-scale climatic circulation (Hurrell, 1995). There is less inter-regional agreement between the precipitation time series in July (Figure 2), possibly indicating more local-scale convective precipitation generating processes in summer (Berg et al., 2009); an exception is some noticeable co-variability between precipitation time series in western Scotland (Figure 2a) and Norway (Figure 2b). The lack of precipitation variability in southern Spain (Figure 2c) reflects the high number of years with no July rainfall, a climatic feature shared amongst a large area surrounding the Mediterranean.
3.2 Field significance

Field significance was assessed to determine if the area (number of MSLP grid points) with observed significant monthly correlation between MSLP and precipitation was larger than what would be expected by chance alone. If this is the case, the month was described as ‘field significant’. The number of months in each season with field-significant correlations between precipitation and MSLP is shown in Figure 3. In winter (December, January and February; DJF) in Figure 3a, coastal European regions (except France) have the largest number of field-significant correlation patterns (e.g. Balkans, Iberian Peninsula and western Scandinavia) suggesting that large-scale atmospheric patterns have a significant influence on coastal European precipitation in winter; this corroborates the findings of Wibig (1999). With increasing distance from the Atlantic Ocean and in the lee of mountain ranges (central and East Sweden, central Britain and in the lee of the European Alps), the number of field significant months decreases because of weaker connection between precipitation and the large-scale atmosphere (Figure 3a). In spring (March, April and May; MAM) and autumn (September, October and November; SON) in Northwest Britain and western Scandinavia, the many months with field significant precipitation grids may indicate that the winter atmospheric circulation exists for a longer duration (Figure 3b and 3d respectively). Fewer field significant precipitation grids are found in summer (Figure 3c) suggesting that more local-scale weather systems produce the precipitation in summer because the observed significant MSLP-precipitation correlation areas exist across smaller geographical regions. The field significant months over the Low Countries (e.g. Netherlands) and Italy/Balkans in July (Figure 3c) indicates a relationship with the SNAO pattern.
3.3. Influence of trends on the correlation analyses

The precipitation and MSLP time series were tested for trends, which may affect the significance of the correlations. Results of the Mann-Kendall test suggest that trends in precipitation time series occur predominantly in winter (January to March). In Scandinavia (Spain), precipitation has an increasing (a decreasing) trend over 1958-2002. Around 45°N (i.e. the Alps) is the transition zone between increasing and decreasing trends. During winter, significant increasing (decreasing) MSLP trends are found near the Azores (Iceland), indicating a tightening of the pressure gradient over the North Atlantic and a stronger zonal (westerly) flow, coincident with a stronger positive phase of the NAO. This is consistent with (Hurrell and Van Loon, 1997); they found that the NAO was often in a positive phase from 1980 until the late 1990s. An increasingly stronger positive NAO could be the cause of the significant increasing (decreasing) precipitation trend observed over Scandinavia (the Iberian Peninsula).

Furthermore, the trend towards a strengthening of the NAO influence on European climate during the last part of the Twentieth Century is thought to be due to an eastward movement (i.e. toward Europe) of MSLP anomalies associated with the NAO (Vicente-Serrano and Lopez-Moreno, 2008).

The influence of trends (in both the precipitation and MSLP time series) on the significance of the correlations was assessed using a bootstrap procedure. Figure 4 shows the empirical bootstrap distribution of the 1000 correlations produced between the grid cell with precipitation time series with the strongest increasing trend (February,
62.25°N 9.75°E; Norway) and the MSLP grid cell with the strongest observed correlation in February ($\rho=-0.667; 70°N 7.5°W$). The 95% percentile of the empirical bootstrap correlation distribution (black vertical line in Figure 4) is less than zero; therefore, the trend does not affect the significance of the observed correlation at this grid point at the 0.05 significance level. Hence, the correlation is significant even without a trend present. Results of the empirical bootstrap distributions at all MSLP grid points for the precipitation grids with significant trends reveals that the significance levels (i.e. 0.05) were almost identical to those obtained through the observed correlation analysis, demonstrating more widely that the presence of trends does not significantly affect the results presented herein.

4. Correlation between MSLP and precipitation

This section presents the correlation analyses of large-scale MSLP with European precipitation. A precipitation grid in western Scotland (57.25°N 5.25°W) is used to illustrate how the correlation results are presented because of this location’s closeness to the westerly flow that results in strong MSLP-precipitation relationships. Figure 5 shows the map of correlations in January between the precipitation time series in western Scotland and the gridded MSLP field across the domain 0°N–90°N and 90°W–90°E (i.e. half of the Northern Hemisphere). This map shows a correlation dipole with significant negative correlation (blue colour) centred over the Norwegian Sea and significant positive correlation (red colour) centred near the Azores. This dipole implies that as MSLP falls to the north and rises to the southwest of the British Isles, precipitation increases in western Scotland, which relates to the Icelandic Low and Azores high pressure systems respectively. Note that the continuous blue colour at high
latitudes (at 90°N) occurs because there is only one MSLP value (i.e. an artefact of the cartographic projection chosen). Following the nested research design adopted, results (with correlation maps similar to Figure 5) are firstly presented for precipitation grid cells in the British Isles (Figure 6) and secondly presented for Europe (Figures 7 – 10) for selected months. It must be stated here that the results presented in Figures 6 – 10 should not be scrutinised in great detail. In these figures the main features of interest are the changes in size and location of the colours (i.e. significant correlation patterns).

### 4.1 Correlation analysis over the British Isles in January

In January across the British Isles, the location of areas with significant correlation between MSLP and precipitation vary both in size and location (coloured areas in Figure 6). In western Scotland, the correlation dipole has significant negative correlation to the north and significant positive correlation to the southwest of the British Isles (as in Figure 5); this relates to the Icelandic Low and Azores High pressure centres, respectively. The large areas of significant correlation between MSLP and precipitation in western British districts (including western Scottish Highlands, the Pennines and Welsh mountains) are due partly to the orographic enhancement of rainfall (Roy, 1997, Sumner, 1997, Tufnell, 1997). Notably, as distance increases from the Atlantic Ocean, the correlation dipole shrinks and areas with non-significant correlation become more prominent, probably due to the shelter from the westerly air flow by western mountain chains. Precipitation in eastern Britain has no significant positive correlation with MSLP to the southwest of the British Isles. Instead, positive correlation is seen with MSLP over central Russia, which could relate to the Siberian High pressure system (Figure 6). This suggests that precipitation is related to an easterly air flow on
the southern edge of the Siberian High. On route to Britain, the easterly flow would be modified becoming moist due to evaporation over the North Sea, which in turn could produce precipitation in northeast England.

4.2 Correlation analysis over Europe in winter

The MSLP correlation dipole seen in January across the western British Isles corresponds with precipitation across northern Norway and Sweden (i.e. across the northwest European boundary with the North Atlantic Ocean; Figure 7). This statistically significant MSLP correlation dipole ($\rho > \pm 0.6$) is strongest in December, January (Figure 7), and February; and it implies that, from the western British Isles through to Scandinavia, precipitation occurs when MSLP is low near Iceland and high near the Azores. This same dipole structure, although smaller in extent (especially for the positive correlation area), is also found across northern continental Europe from northern France to Finland, indicating that precipitation has a positive relationship with the NAO pattern. These results show that a similar large-scale atmospheric circulation generates winter precipitation across northern and western Europe.

From western to eastern Scandinavia, the size of significant MSLP correlation patterns show a distinct west-east gradient, with stronger and larger MSLP influence on precipitation in the west than in the east. The effect of MSLP on precipitation, as characterised by the correlation patterns, is less in central and East Sweden than in western Norway which is likely to be due to the Scandes mountains (between Norway and Sweden) reducing the influence of moist westerly winds from the Atlantic on
central Sweden (Uvo, 2003, Kingston et al., 2009). In southern Finland, where there is a lesser influence of mountains on the atmospheric flow, westerly winds can penetrate further into the European continent, thus bringing precipitation (Uvo, 2003).

From central France southwards, the winter correlation dipole has a reversed pattern compared to northern Europe (as also identified by Bartolini et al., 2009). From the Iberian Peninsula to the Balkans, large regions of negative and positive correlation are centred over the Azores and northern Europe, respectively (Figure 7). This means that as MSLP falls near the Azores and rises near Iceland, a cyclonic circulation affects southern Europe, thus increasing precipitation. This atmospheric circulation is associated with storm tracks that are located further south than normal that would steer rain-bearing depressions into southern Europe (Marshall et al., 2001). South-eastern European (Balkans) precipitation has positive MSLP correlation over Asia, which indicates a link with the Siberian High pressure system. In central and Eastern Europe downwind of the European Alps, smaller MSLP-precipitation correlation patterns occur indicating that the Alps reduce the influence of westerly winds on precipitation in this region.

4.3 Correlation analysis over Europe in spring

With the onset of spring, the pole-to-equator temperature gradient (hence, the westerly air flow) across the North Atlantic weakens. The MSLP-precipitation correlation patterns for April (Figure 8) show that smaller-scale atmospheric circulation patterns are linked with precipitation and the large-scale winter atmospheric patterns have broken
down. However, note that in northern Scandinavia and in the far northwest of Scotland, a North Atlantic correlation dipole still exists in April suggesting that the winter circulation patterns have a longer duration at higher latitudes.

4.4 Correlation analysis over Europe in summer

As summer approaches, the North Atlantic correlation dipole continues to weaken. During summer (June, July, August; JJA), northern European precipitation has no significant positive correlation over the Azores region. In general, precipitation has fewer significant correlations with the MSLP field (larger white areas in Figure 9 in July). During June and July, significant positive MSLP correlation over Greenland is found with northwest European precipitation, and significant negative MSLP correlation over Greenland is found with southern to southeast European precipitation. This means that as pressure falls over Greenland, pressure rises over northwest Europe resulting in precipitation decrease over northwest Europe; this is shown by the positive (red) correlation in the top-left (northwest) of many precipitation grids in Northwest Europe (Figure 9). For southern Europe the negative (blue) correlation areas over Greenland (northwest of each precipitation grid) highlight that as pressure falls over Greenland, pressure falls over the Mediterranean, and precipitation increases over Southeast Europe. Zveryaev (2004) identified summer relationships between precipitation and patterns of high pressure over northwest Europe and low pressure over Greenland and the Mediterranean; this was described as the SNAO. The centres of correlation of MSLP and precipitation shown herein coincide with those of Zveryaev (2004).
The smaller extent of the significant MSLP correlation patterns in summer compared to winter suggests that the large-scale climatic circulation has a lesser influence on summer precipitation. This may be related to the prevalence of convective precipitation events in summer (Berg et al., 2009) that correspond to smaller scale weather systems. Zveryaev and Allan (2010) suggest local processes play a dominant role in summer precipitation occurrence because of an uncovered significant statistical linkage between European precipitation and European land surface evaporation. In our analysis herein, although the temporal (monthly) and spatial (2.5°×2.5°) resolution of the MSLP fields are too coarse to resolve convective activity, the small size of correlation patterns identified with European precipitation in summer is a sign of smaller scale atmospheric dynamics in operation.

### 4.5 Correlation analysis over Europe in autumn

During autumn, the North Atlantic correlation dipole pattern begins to reappear in September in northern Europe; this is visible in October (Figure 10) across western British Isles and Scandinavia. Note that over Scandinavia, the MSLP-precipitation correlation patterns have a more easterly location compared to the western British Isles, which suggests a linkage with the Scandinavian climate pattern (Barnston and Livezey, 1987); the Scandinavian pattern is discussed further in Section 5. The re-formation of the large-scale North Atlantic atmospheric patterns is not found until December in the southern British Isles and northern France (not shown) suggesting that the winter circulation pattern is in place earlier further north where the winter season is longer.
5. Correlation between NAOI and precipitation

The maximum and minimum gridded MSLP-precipitation correlations were compared to the precipitation correlations with the CRU NAOI and EOF NAOI for six selected precipitation time series (as in Figures 1 and 2). Since the NAOI has been used widely as a measure of the strength of the North Atlantic influence on European climate (as reviewed in Section 1), our comparative analysis herein serves to benchmark the gridded MSLP-precipitation correlations. For all six locations, precipitation has stronger correlations with the MSLP than with the NAOI, regardless of season (Table 1 for January; Table 2 for July). This suggests that the NAOI is unable to explain precipitation occurrence as well as MSLP because the centres of strong MSLP correlation do not always coincide with the fixed Azores-Iceland locations defining the NAOI. Note that the CRU NAOI and EOF NAOI provide similar results (Tables 1 and 2). In January (Table 1) northern European precipitation has a positive relationship with the NAOI and southern European precipitation has a negative relationship with the NAOI, as shown by the time series plots in Figure 1 and as also found by Hurrell (1995). Further east (central France and Czech Republic) the NAOI has lower correlation with precipitation reflecting: (a) a reduced oceanic influence on precipitation and (b) the areas of climatic control on precipitation are not co-located with the NAOI definition. In July, only western Scotland and central France have significant NAOI-precipitation correlations (Table 2), possibly reflecting strong maritime influence on western Scottish precipitation due to its close proximity to the Atlantic Ocean, and French precipitation being influenced by the SNAO pattern (Figure 9).
Other climatic patterns that are characterised by simple indices may also be related to European precipitation. In particular, evidence of the Scandinavian pattern (Barnston and Livezey, 1987) can be found in the MSLP-precipitation correlation maps. A positive phase of the Scandinavian pattern has an anticyclone over Scandinavia and weaker cyclonic regions over Western Europe and eastern Russia, which results in lower precipitation totals over Scandinavia and higher precipitation totals over central Europe. For example, precipitation over eastern France in October (Figure 10) shows a positive relationship with the Scandinavian pattern with positive correlations over Scandinavia and negative correlations over Western Europe. In this analysis, however, only the NAOI was used to show that gridded MSLP fields yield stronger statistical relationships with precipitation than this dominant atmospheric mode’s index.

6. Conclusions

This paper has used correlation analysis to assess the spatiotemporal variability of large-scale climatic control (MSLP) on European precipitation. The uncovered significant hydroclimatological relationships have improved understanding of precipitation generating mechanisms in Europe, particularly with respect to large-scale atmospheric circulation. The key conclusions that may be drawn from this work are:

- Throughout the year, European precipitation is associated with MSLP centres of action located over different areas of the Northern Hemisphere, with the winter yielding generally larger regions of significant correlation than the summer. In winter, precipitation shows links with extensive atmospheric areas reflecting the strong influence of the large-scale atmospheric circulation on European precipitation.
(especially in the west). In northern Europe positive correlation exists over the Azores and negative correlation exists near Iceland, implying a positive relationship with the NAO; in southern Europe negative correlation exists over the Azores and positive correlation exists near Iceland, implying a negative relationship with the NAO. These relationships are in agreement with those of Hurrell (1995). These correlation centres relate to the Azores High and Icelandic Low pressure systems.

The large spatial scale of significant atmospheric patterns over Northwest Britain and Scandinavia is thought to be caused in part by orographic effects on precipitation. Downwind from the Atlantic (east of the Scandes or of the Alps), smaller MSLP-precipitation correlation patterns occur, showing a reduced influence of westerly winds on precipitation in these regions.

- In summer, European precipitation has fewer significant correlations with the large-scale climatic circulation, implying that precipitation is produced by local scale and shorter duration weather systems as the atmosphere warms. As this study used a coarse temporal (monthly) and spatial (2.5°×2.5°) resolution of MSLP, convective systems that are a source of summer European precipitation (Berg et al., 2009) would not have been well captured. However, precipitation in some parts of Europe (west of Baltic Sea, northwest Europe and eastern Mediterranean) does show strong correlations with MSLP over Greenland, similar to the SNAO, a variant of the well-established NAO.

- In spring and autumn, smaller MSLP patterns than in winter are associated with European precipitation, with the winter dipole shrinking and moving during spring, to reappear in September in northern Europe. Patterns in MSLP reveal an extended winter season in the far north of Europe (e.g. Scandinavia) as it lingers during
spring, and the Scandinavian climate pattern (Barnston and Livezey, 1987) is identified in the MSLP-precipitation correlation maps over Scandinavia and central Europe in autumn before shifting back to NAO-like dipole in December in the British isles and northern France.

- The gridded MSLP data yield stronger empirical relationships compared to the NAOI (whether defined as fixed dipole or from EOF analysis) because the MSLP can capture the dynamic seasonal movement of the atmospheric areas with strongest control on European precipitation. The geographical points used in the CRU and EOF NAOI definition do not always coincide with the high MSLP-precipitation correlation areas; therefore, the NAOI is a less powerful explanatory variable of European precipitation, even during winter where its links with precipitation had been previously identified. Although atmospheric indices are useful as a starting point in investigating large-scale climatic control on European precipitation variability, the results herein suggest that finer scale (i.e. gridded) data yield stronger statistical relationships and improved understanding of this important socially relevant hydroclimatological process.

- There is a gradient in the influence of North Atlantic pressure systems over Europe, as shown by larger MSLP-precipitation correlation areas in western districts compared to eastern districts (i.e. from west-to-east Britain, across the European Alps and from Norway to central and East Sweden). This reflects the heterogeneities of the European land mass, in particular the barrier effect of mountain chains such as the Scandes or Alps, which limit penetration of eastward-moving rain-bearing systems resulting in smaller precipitation totals in their lee (i.e. rain shadow) and weaker MSLP-precipitation correlation patterns. As the large-scale atmospheric
dynamics are most active in the winter season, this phenomenon is most notable in the winter months.

The recent availability of gridded precipitation and MSLP time series has made it possible to undertake a consistent and systematic spatiotemporal analysis of the large-scale climatic control on European precipitation. The results presented herein corroborate previous research that considered atmospheric indices (e.g. Hurrell, 1995), but our findings demonstrated that an index with fixed-point definition, such as the NAOI, is incapable of explaining precipitation occurrence in certain regions (i.e. central Europe, such as the Czech Republic; Tables 1 and 2) and seasons (i.e. summer). The identified hydroclimatological relationships could be used to evaluate climate model output to determine if the location, strength and timing of these hydroclimatological connections can be reproduced accurately by models. If climate models become capable of reproducing these hydroclimatological correlation patterns at extended forecast lead times, scientific and societal benefits could result.

Figure captions

Figure 1: Monthly standardised time series of January precipitation anomalies in six grid locations across Europe and the station-based CRU NAOI (1958-2002). The areas shown are: a) western Scotland (57.25°N 5.25°W), b) Norway (65.25°N 13.75°E), c) southern Spain (37.75°N 3.75°W), d) central France (47.25°N 3.25°E), e) Czech Republic (49.75°N 15.25°E), and f) Balkans (42.75°N 20.25°E). The CRU NAOI-precipitation Spearman correlations are given for each of the six precipitation grids with the significance level $\alpha$ (NA implies the correlation is not significant at the 0.05 level).

The precipitation time series are solid black lines and the CRU NAOI time series are shaded solid grey.

Figure 2: Monthly standardised time series of July precipitation anomalies (1958-2002) in six grid locations across Europe and the station-based CRU NAOI (1958-2002) [Key as Figure 1].

Figure 3: Number of field significant months for MSLP for (a) winter (DJF), (b) Spring (MAM), (c) summer (JJA) and (d) autumn (SON) (period of study is September 1957 to August 2002).

Figure 4: The empirical bootstrap distribution of the correlation from the 1000 realisations between the February precipitation time series with the strongest increasing trend (62.25°N 9.75°E; Norway) and the MSLP time series (70°N 7.5°W) with the highest observed correlation with precipitation. Black vertical line is the 95% percentile; dashed line is correlation $\rho$=0.
Figure 5: Correlation analysis of precipitation in a single grid in western Scotland (57.25°N 5.25°W; location given by black box) with MSLP across 0°N–90°N and 90°W–90°E in January (1958-2002). Red (blue) colour signifies significant positive (negative) spearman rank correlation (significance level $\alpha = 0.05$).
