(Received 29 June 2016; accepted 29 August 2016; published online 8 September 2016)

We investigate the nonlinear resonant wave-particle interactions including the effects of particle (phase) trapping, detrapping, and scattering by high-amplitude coherent waves. After deriving the relationship between probability of trapping and velocity of particle drift induced by nonlinear scattering (phase bunching), we substitute this relation and other characteristic equations of wave-particle interaction into a kinetic equation for the particle distribution function. The final equation has the form of a Fokker-Planck equation with peculiar advection and collision terms. This equation fully describes the evolution of particle momentum distribution due to particle diffusion, nonlinear drift, and fast transport in phase-space via trapping. Solutions of the obtained kinetic equation are compared with results of test particle simulations. Published by AIP Publishing.

[http://dx.doi.org/10.1063/1.4962526]

Resonant interactions of a particle ensemble with a broad spectrum of low amplitude electromagnetic waves are conventionally described by the diffusion (Fokker-Planck) equation of the quasi-linear theory.9,22 The timescale of the resonant wave-particle interactions is then defined by the inverse of the finite wave-packet dispersion rate.12,17 In inhomogeneous plasmas (or background magnetic field), an additional stochasticization of the resonant charged particle motion introduces a new timescale of the wave-particle interactions19,20 and justifies the applicability of the quasi-linear diffusion equation even for a very narrow wave spectrum.1 One of the most successful examples of application of the quasi-linear theory is the very accurate description of relativistic electron acceleration and scattering in the Earth’s radiation belts. However, when the wave amplitudes become sufficiently high, the applicability of the quasi-linear approach breaks down17 and the nonlinear effects such as particle trapping and nonlinear scattering (phase bunching)11,15 start to play an important role. These effects are well studied and described analytically for test particle trajectories (e.g., Refs. 2, 3, 6, and 18), but the problem of their proper inclusion into a Fokker-Planck equation for a full description of the long-term evolution of a particle ensemble has, so far, eluded solution (e.g., see discussion in Ref. 16).

If the wave field energy is much smaller than the particle kinetic energy, the wave-particle interactions are described by the Hamiltonian $H = H_0 + \varepsilon H_1 \cos \phi$ where the unperturbed Hamiltonian $H_0$ describes particle motion in the background magnetic field, and the wave-induced perturbation $\varepsilon H_1 \cos \phi$ depends on the wave phase $\phi$ (where the weakness of perturbations is taken into account via the small parameter $\varepsilon \ll 1$). Unperturbed motion consists of several types of oscillations (gyrorotation around the background magnetic field, bounce oscillations between magnetic mirror points, etc., e.g., Ref. 20). If one of these oscillations turns out to be faster than the wave phase variation (which rate $\dot{\phi}$ is about the wave frequency $\omega$), the perturbation should be expanded in harmonics of this oscillation $H_1 \cos \phi = \sum_n H_1^{(n)} \cos \phi^{(n)}$, where each harmonic can be considered separately (later we omit index $n$).20 The phase $\phi$ varies much faster than other variables, and we assume for simplicity that its rate $\dot{\phi} \sim 1/\varepsilon$ (in the general case, $\dot{\phi}$ is a large parameter independent of $1/\varepsilon$, but for most important cases, the temporal variation of the perturbation $\partial(H - H_0)/\partial t \sim \phi$ should be about $O(1)$ to significantly affect particle motion). It is convenient to introduce a new variable $\psi$ and to consider the pair of conjugate variables $(\phi, I)$, where $I$ is the particle normalized momentum.2,3,18 Changing the timescale $t \rightarrow t\varepsilon$, we obtain a system where phase changes at a rate $\sim 1$, whereas other variables (momenta and coordinates) evolve over the timescale $\tau = t\varepsilon$. To parameterize the dependence of $H$ on these slow variables in terms of dependence on $\tau$, we consider a simple but rather general $1\frac{1}{2}$ degrees of freedom system with Hamiltonian $H = H_0(\tau, I) + \varepsilon H_1(\tau, I) \cos \phi$. The resonant condition $\dot{\phi} = \partial H_0/\partial I = 0$ has a solution $I = I_\phi(\tau)$. Expansion around $I_\phi$ gives the following Hamiltonian:

$$H = \Lambda + \frac{1}{2} \varepsilon^2 (I - I_R)^2 + \varepsilon B \cos \phi, \quad (1)$$

where $\Lambda(\tau) = H_0(\tau, I_\phi(\tau))$, $\gamma(\tau) = (\partial^2 H_0/\partial I^2)_{I=I_\phi}$, $B(\tau) = H_1(\tau, I_\phi(\tau))$. We introduce the new variable $P_\phi = (I - I_R)$ and rewrite the new Hamiltonian $\mathcal{F}$ of perturbations $H - \Lambda$ in a form

$$\mathcal{F} = \frac{1}{2} \varepsilon P_\phi^2 + \varepsilon \Lambda \phi + \varepsilon B \cos \phi, \quad (2)$$

where $\varepsilon \Lambda = \partial I_R/\partial \tau$ and $(\phi, P_\phi)$ are conjugate variables. The general Hamiltonian (2) describes resonant systems with fast phase (see a general derivation of this Hamiltonian in

PHYSICS OF PLASMAS 23, 090701 (2016)
Ref. 14). The corresponding Hamiltonian equations \( \dot{P}_\phi = -eA + eB \sin \phi, \dot{\phi} = gP_\phi \) describe the nonlinear pendulum with a torque that appears in the majority of systems describing wave-particle resonant interactions (see, e.g., reviews 2–4, and 18 and references therein). The analysis of the Hamiltonian (2) will provide the needed characteristics of particle scattering and acceleration by the waves. Below we consider only sufficiently intense coherent waves such that \( B > |A| \).

For \( a(\tau) = B/|A| > 1 \) (for definiteness, we consider \( B > 0 \) and \( g > 0 \)), the phase portrait of Hamiltonian (2) contains a region filled with closed trajectories. The existence of such a region guarantees the nonlinear character of wave-particle interaction (see more details in Refs. 2, 3, and 18). Particles moving along closed trajectories oscillate around the resonance \( \phi = 0 \) and are called trapped particles. Particles moving along open trajectories are transient and are scattered by the wave. If the area of the trapped region grows, some transient particles can get trapped into resonance with the wave. \( S \) is given by equation (see Eq. (2))

\[
S(a) = \int_{\phi_-}^{\phi_+} \sqrt{a^2 - \sin^2 \phi} \cos \phi d\phi, \quad (3)
\]

and \( \phi_- \) is a root of equation \( a \sin \phi = -1 \), whereas \( \phi_+ \) is a root of equation \( (\phi_+ - \phi) + a \cos \phi_+ - \cos \phi = 0 \). The relative number of particles which can be trapped by waves during one passage through resonance is called the probability of trapping \( \Pi \) and is defined as a ratio of \( dS/dt \) and phase flux through the resonance \( \Phi \)

\[
\Pi = \frac{dS}{dt} \left| \int_0^{2\pi} \frac{P_\phi d\phi}{2\pi |A|} \right| = \frac{1}{2\pi |A|} \frac{dS}{dt}, \quad (4)
\]

where \( \dot{F}_\phi \) is defined by Hamiltonian equations for (2), and \( \Pi = 0 \) if \( dS/dt < 0 \). Both \( S \) and \( \Pi \) are small variables \( \sim \sqrt{a} \).

Once being trapped, particles move in resonance with the wave until the area \( S(\tau) \) returns to its value at the moment of trapping \( \tau_{\text{trap}} \) (see scheme in Fig. 1). During the time interval of trapped motion, particle momentum \( I \) varies as \( I_0 \), and particles escape from resonance with larger (or smaller) \( I \) or larger (smaller) energy \( H(I, \tau) \). This effect corresponds to particle acceleration via trapping.\(^2,3,16,18\) Since the duration of trapping acceleration can be rather long and variations of \( I \) can be large (both being independent of \( e \)), this process cannot be described as a local diffusion.

Transient particles passing through the resonance without being trapped are scattered with a change of momentum \( I \) given by equation \( \Delta I = \int \dot{I}dt = \sqrt{2eB/gh} a (\phi^\ast, a) \), where

\[
h(\phi^\ast, a) = \frac{\text{sign}(A) \sqrt{a \sin \phi} d\phi}{\sqrt{\phi^\ast - \phi + a(\cos \phi^\ast - \cos \phi)}}, \quad (5)
\]

and \( \phi^\ast \) is defined by the particle energy \( F^\ast = e|A|(\phi^\ast + a \cos \phi^\ast) \) taken at \( P_\phi = 0 \). The integral (5) depends on \( \tau \) and \( \theta = (\phi^\ast + a \cos \phi^\ast)/2\pi \). The function \( h(\theta) \) is periodic (see, e.g., Ref. 3), whereas the mean value \( \langle h \rangle_0 = -\text{sign}(A)s(a)/\pi \) for \( a > 1 \) and \( \langle h \rangle_0 = 0 \) for \( a < 1 \) (see Ref. 14). For wave-particle interactions in a magnetic field, averaging over initial conditions (gyrophases) of resonant particles is equivalent to an averaging over \( \theta \). This allows us to derive two expressions describing the evolution of the \( \theta \)-averaged particle distribution \( f(I) \) under the influence of nonlinear and quasi-linear scattering.\(^5\) The velocity of drift \( V = \langle \dot{I} \rangle/\tau_0 = -\text{sign}(A)S/2\pi \tau_0 \) and the diffusion coefficient \( D = \text{Var}(\Delta I)/\tau_0 = 2e(B/g)\text{Var}(h) \), where \( \tau_0 \) is the time interval between two successive passages through the resonance and \( \text{Var} \) is the variance. This expression for the diffusion coefficient \( D \) coincides with the formula derived previously for a narrow wave spectrum in the frame of the quasi-linear theory.\(^1\) Coefficients \( \Pi(\tau), V(\tau), D(\tau) \) can be rewritten as \( \Pi(I), V(I), D(I) \) because \( I = I_0 \) at resonance.

We have derived expressions for \( \Pi(I), V(I), \) and \( D(I) \). These general characteristics of nonlinear wave-particle resonant interaction have been derived analytically and tested numerically many times for different plasma systems.\(^1,3,16,18\) However, to our best knowledge, no equation providing the relationship between \( \Pi \) and \( V(I) \) has been yet available. Hereafter, we shall derive this relationship and use it to construct (for the first time) a generalized Fokker-Planck equation which will include all effects described by \( \Pi(I), V(I), \) and \( D(I) \). Using the definition \( e\dot{\phi} = \partial I/\partial \tau \) and Eq. (4), we obtain

\[
\frac{dV}{dt} = -\frac{\text{sign}(A) dS}{2\pi \tau_0} \left( \frac{d\tau}{dI} \right)^{-1} = -\frac{1}{2\pi \tau_0} \frac{dS}{dI} = -\frac{\Pi}{\tau_0}. \quad (6)
\]

Using the above-defined \( D, V, \) and \( \Pi/\tau_0 \) and considering a trapping/escape event as a rapid change of particle \( I \) to \( I' \) (where \( I' \) is defined by equations \( I' = I_K(\tau_{\text{esc}}), S(\tau_{\text{esc}}) = S(\tau_{\text{inv}}) \), see Fig. 1), we can now write a Fokker-Planck equation describing the full evolution of the distribution.
where function \( f(I) \) under the influence of both scattering and trapping (the diffusion term being written in its divergent form)

\[
\frac{df}{dt} = \frac{\partial}{\partial l} \left( D \frac{\partial f}{\partial l} \right) - \frac{\partial f}{\partial l} \frac{dV}{dI} + \int_{0}^{\infty} \left( f(I)Q_{I-I} - f(I)Q_{I-I} \right) dI,
\]  

where particle transport \( I' \to I \) via trapping is defined by probability \( Q_{I-I'} \) and particle departure from \( I \) by probability \( Q_{I-I'} \). Let us consider \( S(t) \) rewritten as \( S(I) \) with monotonous \( P_{I} \) and assume for simplicity that \( S \) has only one maximum at \( I_{R} = I_{0} \) (see Fig. 1). At resonance \( I = I_{R} \), and thus \( S = S(I) \). For \( I > I_{0} \) we have \( S \) growing and a finite probability of trapping \( Q_{I-I} = (\Pi(I)/\tau_{0}) \delta(I-I') \). For \( I < I_{0} \), the area \( S \) decreases and particles escape from resonance. The corresponding function is \( Q_{I-I} = (\Pi(I)/\tau_{0}) \delta(I-w(I')) \), where function \( w(I') \) gives the value \( I' > I_{0} \) that particles should have when getting trapped to escape later from resonance with \( I < I_{0} \) (\( w \) is defined by the \( S(I) \) profile, see Fig. 1), and \( \Pi(I') \) is the probability of particle trapping at \( I' > I_{0} \). The integral operator in Eq. (7) can then be re-formulated as \(-f(I)\Pi(I)/\tau_{0} \) for \( I > I_{0} \) and \( f(I')\Pi(I')dw/dI'/\tau_{0} = (dV/dI)f(I') \) for \( I < I_{0} \), where we used

\[
\frac{dw(I')}{dI'} = \frac{dl}{dI'} = \frac{dV(I')/dI'}{dV(I)/dI} = -\Pi(I')/\tau_{0}
\]

and \( V(I') = V(I) \) because \( S(\tau_{trap}) = S(\tau_{esc}) \). Using these expressions and Eq. (6), we can rewrite Eq. (7) in its final form

\[
\frac{df}{dt} = \frac{\partial}{\partial l} \left( D \frac{\partial f}{\partial l} \right) - f \frac{dV}{dI} + (f-f(I'))(I', I, l, d, t, \cdots),
\]

where \( I = w(I') \), \( \Theta(I) = 1(0) \) for \( I > I_{0}(I < I_{0}) \). Equation (8) is a Fokker-Planck equation generalized to include effects of nonlinear scattering (drift V) and fast transport in phase space (nonlocal term \( \sim f(I) - f(I') \)). The timescale of diffusion is \( e^{-1} \) (since \( D \sim e \)), whereas the timescales of drift and trapping-induced transport are much shorter \( \sim e^{-1/2} \). For systems with small wave amplitudes \( \alpha < 1 \), \( V \) and \( dV/dI \) vanish and Eq. (8) reduces to the usual quasi-linear diffusion equation.

To check Eq. (8), we compare its solution with results of numerical trajectory integration for the initial system (1). We consider a simple example of Hamiltonian (1) with \( \Lambda = 0 \), \( g = 1 \), \( I_{R} = \sin \tau \), and \( B(\tau) \) a periodic function of \( \tau \) (period is \( \tau_{0} = 2\pi/\nu \)) with a single maximum over \( \tau \in [\tau_{0}/4, 3\tau_{0}/4] \) and equals to zero for \( \tau \in [0, \tau_{0}/4, [3\tau_{0}/4, \tau_{0}] \). The resonant momentum \( \tau_{R} \) varies from \(-1 \) to \( 1 \) and particles with all \( I \in [-1, 1] \) pass through the resonance over one period \( \tau_{0} \). Figure 2 shows two examples of test trajectories calculated over a long time interval. Particles can be trapped at a positive \( I \) and transported to negative \( I \) (in this system \( I_{0} = 0 \)), whereas nonlinear drift \( V \) transports particles back from negative \( I \) to positive \( I \). Both processes of trapping and drift coexist with diffusive scattering. Particle behavior shown in Fig. 2 is a typical behavior in plasma systems with nonlinear wave-particle interactions (see, e.g., trajectories in Refs. 3 and 16).

For our test system, we calculate \( \Pi \) from Eq. (4), \( \tau_{0} \nu = -\sqrt{8\nu B_{s}(\alpha)/2\pi} \) from Eq. (3), diffusion coefficient \( D \), and function \( w(I) \), and express them as functions of \( I = I_{R} \) from Eq. (4). To check the analytical formulas for \( \Pi \), \( V \), and \( D \), we integrate numerically \( 10^{7} \) trajectories with different initial \( I \) and calculate changes \( \Delta \) over one period \( \tau_{0} \) (i.e., for a single resonant interaction). The ratio of the number of particles which were trapped into resonance over the total number of particles gives the numerical probability of trapping \( \Pi \). For untrapped particles, we calculate the average value of \( \Delta \) and its variance \( \text{Var}(\Delta) \). These two functions, depending on the initial \( I \), are then used to calculate the numerical \( V \) and \( D \). Figure 3 demonstrates that our analytical expressions provide quite accurate descriptions of the trapping probability, drift velocity, and diffusion coefficient.

FIG. 2. Two test trajectories (shown by black and red lines) for Hamiltonian (1).

FIG. 3. Comparisons of analytical expressions for \( \Pi_{0} = \Pi_{0}/\sqrt{\nu}, V_{0} = V_{0}/\sqrt{\nu}, \) and \( D_{0} = D_{0}/\nu \) (black curves) with numerical results (red circles).
The above analytical coefficients $V$ and $D$ have been substituted into Eq. (8), which was solved numerically for a particular initial distribution $f_0(I)$. This solution is compared in Figure 4 with the results of direct numerical integration of $10^7$ test particle trajectories for Hamiltonian (1). All three expected effects of trapping and scattering are recovered: (1) fast transport of trapped particles from the initial distribution peak at positive $I_t$ toward negative $I_t$; (2) particle nonlinear drift toward positive $I$; and (3) a slower diffusive flattening.

Based on the successful comparisons displayed in Fig. 4, we can conclude that Eq. (8) accurately describes all the effects of nonlinear as well as quasi-linear wave-particle interactions. This new equation can therefore be considered as a generalization of the classical Fokker-Planck equation derived in the restricted frame of quasi-linear theory. Moreover, its practical, analytical form allows a much faster resolution than with particle simulations, while retaining all the complex and entangled variations. Using the same proposed approach, a more general 2D form of Eq. (8) could be derived, allowing swift calculations of the evolution of particle energy and pitch-angle distributions in many plasma systems where wave intensity and coherency are sufficient to drive nonlinear interactions, as in the Earth’s radiation belts$^{2,3}$ and magnetized laboratory plasmas,$^{7,21}$ inertial confinement fusion,$^{4,10}$ or Penning-Malmberg traps.$^{5,13}$
