Abstract. A vinyl-terminated Polycaprolactone has been developed for tissue engineering applications using a one-step synthesis and functionalization method based on Ring Opening Polymerization (ROP) of ε-caprolactone, with Hydroxyl Ethyl Vinyl Ether (HEVE) acting both as the initiator of ROP and as photo-curable functional group. The proposed method employs a catalyst based on Al, instead of the most popular Tin(II) 2-ethylhexanoate, to reduce the cytotoxicity. Following the synthesis of the vinyl-terminated polycaprolactone, its reaction with Fumaryl Chloride (FuCl) results in a divinyl-fumarate polycaprolactone (VPCLF). The obtained polymers were thoroughly characterized using Fourier Transform Infrared Spectroscopy (FTIR) and gel permeation chromatography (GPC) techniques. The polymer has been successfully employed, in combination with N-vinyl Pyrrolidone (NVP), to fabricate films and computer-designed porous scaffolds by micro-stereolithography (µ-SL) with Gyroid and Diamond architectures. Characterization of the networks indicated the influence of NVP content on the network properties. Human Mesenchymal Stem Cells (hMSCs) adhered and spread onto VPCLF/NVP networks showing good biological properties and no cytotoxic effect.

Keywords: Photocrosslinkable polymer, Polycaprolactone fumarate, biocompatibility, stereolithography, cell-material interactions, mathematically defined scaffold.

1. Introduction

Tissue engineering can provide a way to regenerate damaged tissue (Park et al., 2012; Guarino et al., 2012 a; Catauro et al., 2007). One of the most important considerations in tissue engineering is the scaffold used to provide support to the cells and to regulate cell biology and development into complex three-dimensional (3D) structures (Dhariwala et al., 2004, Ronca et al., 2013; Gloria et al., 2009). RP, also known as Solid Freeform Fabrication, is a group of techniques that creates 3D objects through repetitive deposition and processing of material layers using computer-controlled equipment (Yeong et al., 2004; De Santis et al., 2013; De Santis et al., 2011). Rapid prototyping
technologies and computer-aided design (CAD) enable the precise control over pore
gometry and the design of 3D structures for the preparation of tissue engineering
scaffolds (Eloma et al., 2013; Guarino et al., 2012). Among the rapid prototyping
techniques, stereolithography represent the most versatile method providing the highest
precision and accuracy (Ronca et al., 2012). The key principle of stereolithography is
the spatially controlled solidification of a photo-polymerizable resin. Using a computer-
controlled laser beam or digital light projection, and a computer-driven support
platform, 3D object can be manufactured in a layer-by-layer manner (Melchels et al.,
2009; Sun et al., 2005). By projecting a two-dimensional pixel-pattern through a
transparent plate, a complete layer of resin can be cured at once according to complex
plane pattern. (Pham et al., 1998). Most of the available resin are based on low-
molecular weight, acrylate monomers (Ronca et al., 2013; Eloma et al., 2013, Melchels
et al., 2010). These materials are predominantly glassy, rigid and brittle. Only few
resins have been described that allow the preparation of elastomeric objects by
stereolithography (Bens et al., 2007). The functionalization of aliphatic polyesters, such
as Polyglycolide (PGA), Polylactide (PLA), Poly (ε-caprolactone) (PCL), with
unsaturated groups and subsequent Ultraviolet (UV) crosslinking has been introduced to
overcome this limitation (Grijpma et al., 2005; Sawhney et al., 1993). Photo-curable
functional groups, such as methacrylate have been used most often as unsaturated group
attached on precursor oligomers (Liow et al., 2009; Storey et al., 1993). However, the
diffusion of unpolymerized methacrylates is one of the most important factors causing
irritation in tissues (Yoshii et al., 1997; De Santis et al., 2010). Many studies have found
that substances leached out from acrylic resin can cause, inflammation, or even an
allergic reaction (Jorge et al., 2003; Kedjarune et al., 1999). To overcome these
problems, we are investigating an alternative divinyl-fumarate PCL expected to have a
lower level of toxicity and skin sensitization as compared to acrylate (Blyler et al.,
1999). Synthesis and vinyl functionalization can be achieved in one step, by using ring
opening polymerization (ROP). Hydroxyethyl Vinyl Ether (HEVE) was employed to
play the role of the ROP initiator, and to introduce a photo-curable vinyl functional
group (Lioe et al., 2009). A subsequent reaction with fumaric acid allows the
introduction of a fumarate group, in order to have a tri-functional macromer suitable for
UV curing (Grijpma et al., 2005). The most common initiator for ROP of ε-CL is
Stannous Octanoate Sn(Oct)₂. Although very efficient, its cytotoxicity has recently
caused deep concern about biosafety of the materials synthesized from it and used for
implantation purpose (Albertsson et al., 2000; Kricelj et al., 2000). In this work, a
Sn-free catalyst based on Al has been used in the polymerization of CL achieving more
than 95% monomer conversion at room temperature (Akatsuka et al., 1995). In addition
to chemical-physical characterization, in vitro cytotoxicity and biocompatibility of the
crosslinked materials in direct contact with human mesenchymal stem cells (hMSCs)
were also studied, to validate the potential utility of this innovative tri-functional
polymer in tissue engineering applications.
2. Materials and methods

2.1. Materials

All manipulations of both air and moisture sensitive compounds were performed under a protective atmosphere (nitrogen or argon) using Schlenck techniques or in a glove box. ε-Caprolactone (ε-CL) was purchased from Aldrich and further dried before use by 4Å molecular sieves. Dichloromethane dry was purchased from Aldrich and used as received. The Al catalyst was prepared by reacting Trimethylaluminum (10% weight solution in toluene) with 2 equivalents of 2,6-diter-butyl-4-methylphenol (both reagents purchased from Aldrich). N-Methyl-2-Pyrrolidone (NMP) and N-Vinyl-Pyrrolidone (NVP) were purchased from Sigma-Aldrich (The Netherlands) and employed without further purification. The UV photoinitiator Lucirin TPO-L (ethyl-2,4,6-trimethyl-benzoylphenylphosphinate) was a gift from BASF, Germany.

2.2. Synthesis of divinyl fumarate

A Sn-free catalyst based on Al has been used in the polymerization of ε-CL at room temperature, similarly to the procedure described by Liow et al., with the modification of the initiator used. Here the 2-Hydroxyethyl Vinyl Ether (HEVE) as photocurable initiator has been used (Liow et al., 2009). The polymerization reaction was performed in a Schlenk tube under a nitrogen atmosphere, at room temperature overnight under magnetic stirring, then quenched by addition of methanol. The precipitated PCL was filtered out, washed with further methanol and dried in a vacuum oven overnight at 40°C. After the synthesis of the vinyl-terminated PCL (VPCL, Mw=1.5 kDa), the polymer was reacted with fumaryl chloride, resulting in a divinyl-fumarate polycaprolactone. As showed in Figure 1 the chains contain three photocrosslinkable vinyl units: two at the ends and one in the middle of the chain. By adjusting the ε-CL to HEVE ratio, the number average molecular weight $M_n$ of the vinyl precursor could be easily controlled to achieve a range between 2000 and 5000 g/mol. Three different molecular weights (namely as VPCLA, VPCLB and VPCLC) and one divinyl fumarate polycaprolactone (VPCLF) were achieved as reported in Table 1. Lower molar weight PCL (1.5kDa, VPCLC) was used for the fumarate reaction, this choice was driven by the requirement of a low viscosity suitable for the stereolithographic process.

2.3. Characterization of divinyl-fumarate polycaprolactone macromers

2.3.1. Gel permeation chromatography (GPC). The synthesized VPCLX (where X represent A, B and C) and VPCLF macromers were characterized with respect to molecular weight and molecular weight distribution by Gel Permeation Chromatography (GPC) in THF solution (1mg/ml) at room temperature using a GPC/SEC (Agilent Technologies 1260 Infinity).

2.3.2. Fourier transform infrared spectroscopy (FTIR). Fourier transform infrared (FTIR) spectroscopy (Nicolet 5700, FTIR spectrometer ) was implemented to identify
the functional groups of VPCLX. KBr disks was realized using 2 mg of polymer powder compacted with 200 mg of KBr in a hydraulic press. Spectra were recorded in the 400–4000 cm\(^{-1}\) region (4 cm\(^{-1}\) resolution, averaging 64 scans).

2.3.3. Differential scanning calorimetry (DSC). Thermal properties were evaluated by Differential Scanning Calorimetry (DSC – TA Instrument Q1000). The specimens (8-10 mg) were heated from 30°C to 80°C at 10°C/min, cooled from 80°C to -80°C at 10°C/min and then re-heated up to 80°C at 10°C/min. Melting temperatures were calculated from the second heating scan and reported in Table 1.

2.3.4. Photodifferential scanning calorimeter (pDSC). Q1000 (TA Instruments Waters LLC, New Castle, DE, USA) was used to investigate the kinetics of photopolymerization of functional group present in VPCLX and VPCLF. Pulverized VPCLX and VPCLF were dissolved in two solvents; non-photoreactive NMP and photoreactive NVP respectively. The UV light source was a 200 W high pressure mercury lamp, providing a wavelength spectrum range of 250–650 nm. Prior to the UV exposure samples were subjected to 5 minute isothermal treatment at 60°C. A nitrogen flux of 50 cm\(^3\)/min assured homogeneity of temperature distribution in the measuring cell. Photocurable polymer (3±1 mg) were placed in open aluminum pans and they were exposed to UV light intensity of 50 mW/cm\(^2\) for 15 minutes at constant temperature of 60°C.

2.4. Photo-crosslinking of divinyl-fumarate macromers
The reactivity of divinyl-fumarate macromers is significantly lower if compared to acrylate-functionalized oligomers, and N-Vinyl Pyrrolidone (NVP) is usually used as a crosslinking agent (Dome et al., 1991; He et al., 2001]. Networks were formed from VPCLF by UV irradiation (365 nm) and a biocompatible initiator (Lucirin TPO).

The NVP content was varied from 30 to 50 wt % and the influence of NVP on the network was evaluated. Briefly 5wt% of Lucirin TPO (relative to macromers) was dissolved in the desired amount of NVP by magnetic stirring and then the VPCLC-F macromers were added to the solution. The mixture was placed in an oven at 50-60 °C in order to completely dissolve the macromers. The reactive solution was poured in a Teflon mold and irradiated by UV light for 30 min at a distance of 5 cm. Diluent, unreacted macromers, t and photoinitiator were extracted from the crosslinked network using water and a 3:1 (vol/vol) mixture of isopropanol and acetone. The films were then dried in oven at 60°C for 1 day under vacuum.

2.5. Gel content and water uptake
Gel content studies were performed using Tetrahydrofuran (THF). To determine the gel content of the prepared networks, VPCLF/NVP disk specimens (Φ=6mm, h=2mm) were weighed (m\(_0\)), they were placed into 50 ml THF for 2 days and then dried and weighed again (m\(_1\)). The gel content was defined as:
For water uptake measurements, specimens of extracted networks (n=4) were weighed (m_d) and equilibrated in distilled water for 1 day at 37°C. The samples were removed from the water, blotted dry, and weighed again (m_s). The water uptake was calculated using the following equation:

\[
\text{Water uptake} = \left( \frac{m_s - m_d}{m_d} \right) \times 100
\]

(2)

2.6. Biological characterization

2.6.1. hMSC expansion, seeding and culture. Biological assays were carried out using human mesenchymal stem cells line (hMSCs, LONZA, Milano, Italy). hMSCs were cultured in 75 cm^2 cell culture flask in Eagle’s alpha Minimum Essential Medium (α-MEM) supplemented with 10% fetal bovine serum (FBS), antibiotic solution (streptomycin 100 mg/mL and penicillin 100 U/mL, Sigma Chem), and 2 mM L-glutamine. hMSCs from passages 4 through 6 passage were incubated at 37°C with 5% CO_2 and 95% air. VPCLF/NVP disk specimens (Φ=6mm, h=2mm) were cut from photocrosslinked films and were prepared for cell seeding by first soaking in 70% ethanol (1h) and then 1% antibiotic/antimycotic in phosphate-buffered saline (PBS) (2h), and pre-wetting in medium (2h). 15 × 10^4 cells, re-suspended in 50 µl of medium, were statically seeded onto the scaffold. After seeding, the scaffolds were placed in 48-well culture plates (1 scaffold per well) and, incubated for 2 h in a humidified atmosphere (37 °C, 5% CO_2). After the initial 2 h for cell attachment to the pre-wetted scaffolds 1.5 ml of cell culture medium was added. Scaffolds were maintained in culture for 2 day. Successively, the materials were rinsed twice with PBS, culture medium and unattached cells were removed. The remaining cells were then fixed using formalin (4% formaldehyde in water) for 15 min and then washed with PBS. The samples were stained with hematoxylin and washed twice in distilled water. Cell morphology spreading pattern interaction of hMSC onto VPCLF/NVP specimens were evaluated by confocal laser scanning microscopy (LSM 510, Carl Zeiss).

2.6.2. Alamar blue assay. Cell viability and proliferation were evaluated by the Alamar blue assay. Such technique is based on a redox reaction that occurs in the cytosol of the cells and quantifies the redox indicator which changed to a fluorescent product in response to the chemical reduction by mitochondrial enzymes such as flavin mononucleotide dehydrogenase, flavin adenine dinucleotide dehydrogenase, and nicotinamide adenine dinucleotide dehydrogenase. Furthermore a redox phenomenon gave a quantitative indication of metabolic activity of live cells. The cell–scaffold constructs were removed from the culture plates at days 1,7,10 and 14, rinsed with PBS
For Peer Review

(HyClone, UK) and placed in 48-well culture plates. 1mL of alamar blue diluted 1:10 in phenol red-free medium was added to each well and incubated for a further 4 h at 37°C, 5% CO₂. Successively, 200µL of this solution was transferred into a 96 well plate for the colorimetric analysis. Wells without any cells were used to correct any background interference from the redox indicator. The optical density was measured with a spectrophotometer (Victor X3, PerkinElmer, Massachusetts, USA) at wavelengths of 540 and 600 nm. The number of viable cells is correlated with the level of dye reduction and it is expressed as “percentage of reduction” (%AB reduction), according to the manufacturer’s protocol. Moreover, the number of viable cells on the 2D support was determined by comparing the absorbance at different culture times with a calibration curve obtained by correlating known cell numbers in the 24-well culture plates with the corresponding absorbance values. The culture medium was changed every two days.

2.7. Mathematically defined scaffolds
Stereolithography is a layer-by-layer fabrication method. Complex structures can be built by illuminating sequential layers of a polymerizable resin using digital pixel masks or arrays of mirrors Lucirn TPO-L photo-initiator (5 wt%) and Orasol Orange G dye (0.1 wt%) were added to a solution containing 50 wt% VPCLF and 50 wt% NVP. This resin was used to prepare porous structures by stereolithography with a commercially available set-up (Perfactory Mini Multilens, EnvisionTec). In order to design a suitable scaffold for tissue engineering our approach was to use the family of Triply Periodic Minimal Surfaces (TMPS) as pore morphology. This advanced approach consists on designing sophisticated 3D porous structures using the periodicity of trigonometric equations. The idea was to try to simulate the complex design of models frequently encountered in the nature such as minimal surface architecture (Melchels et al., 2010). In addition, TMPS based scaffolds offer high porosity and pore interconnection that might be beneficial for tissue regeneration independently of the scaffold complexity (Yoo et al., 2011; Rajagopalan et al., 2006). K3DSurf software (http://k3dsurf.sourceforge.net) was employed to generate CAD-files describing the surfaces of Gyroid (G) and Diamond (D) architectures (Gandy et al., 2000; Gandy et al., 1999). The following trigonometric functions with boundary conditions \( x, y = [-6\pi,6\pi] \) and \( z = [-3\pi,3\pi] \) were used:

\[
G: \cos(x) \cdot \sin(y) + \cos(y) \cdot \sin(z) + \cos(z) \cdot \sin(x) = C
\]  

\[
D: \sin(x) \cdot \sin(y) \cdot \sin(z) + \sin(x) \cdot \cos(y) \cdot \cos(z) + \cos(x) \cdot \sin(y) \cdot \cos(z) + \cos(x) \cdot \cos(y) \cdot \cos(z) = C
\]  

To develop porous structures with a porosity of approximately 50-60%, offset values (C) of 0.5 and 0.2 are required for Gyroid and Diamond architectures, respectively. Then, all CAD files were converted to STL files and sliced into 2D sections, each
having 25µm layer thickness, through the Envisiontec Perfactory RP 2.0 software. At the end of the fabrication process uncured resin were removed with Acetone and the scaffolds were postcured in oven at 90°C for 24h under vacuum.

2.8. Morphological characterization of scaffolds
Scanning electron microscopy (SEM) was performed to obtain qualitative information related to the morphology and pore characteristics of the manufactured VPCLF/NVP structures. The specimens were gold sputtered and observed with a FEI QUANTA 200 FEG scanning electron microscope. As nondestructive structural analysis, micro-computed tomography (µ-CT) was performed using a SkyScan 1172 micro-CT scanner (Bruker) at 5.45 µm resolution. Scaffolds were mounted on a rotary stage and were scanned at an X-ray tube voltage of 59 kV, a current of 167 µA and a rotation angle of 180°. A two-dimensional (2D) detector records projections of the sample for different angular positions. For the present study 1187 projections within an angular range of 180° were taken. The exposure time was 200 ms per projection. The images were recorded on a 2048 2048 CCD detector, with the pixel size set to 5.45 µm. The 3D structure was finally reconstructed using a filtered back-projection algorithm. A volume of interest was reconstructed for each sample; a single voxel of the reconstructed image had a size of 5.45 x 5.45 x 5.45 µm³. SkyScan CT-analyzer biomedical image software were used to generate 3D images to show the distribution of phases.

3. Results and discussions
In this work we synthesized a tri-functional photocrosslinkable PCL by using HEVE in the presence of a novel Sn-free catalyst based on Al. The resulting divinyl-fumarate PCL network was characterized by its molar weights, functional end groups and transition temperatures, using several techniques including GPC, NMR, FTIR, DSC and pDSC.

3.1. Synthesis of divinyl fumarate PCL
The polymerization of ε-caprolactone with the methylaluminum bis(2,6 ditertbutyl-4-methylphenolate) system proceeded smoothly at room temperature to give a polyester showing a reasonably narrow molecular weight distribution (MWD). To enable photocuring of PCL, a monofunctional vinyl ether was incorporated into each PCL chain. The resulting polymers, isolated by pouring the polymerization mixture into MeOH/H2O solution (50/50 vol/vol), had an Mw/Mn ratio that varied from 1.31 for the VPCL A to the 1.48 of the VPCLB. Also the Mn measurements closely matched the theoretical values (Mn,th) as it is shown in Table 1. PCL with a range of molecular weight ranging from 1.5 - 6 kDa were successfully synthesized but only the lower molar weight PCL (1.5kDa, VPCLC) was used for the following fumarate reaction. Low molar weight vinyl-PCL was reacted with fumaryl chloride to obtain a tri-functional photocurable polycaprolactone. The FTIR spectra of VPCLc before and after the reaction with fumaryl chloride are shown in Figure 2. The absorption bands with peaks
positioned at 2947 and 2866 cm$^{-1}$, a common feature of VPCL and VPCLF spectra, are due to the stretching of the methylene groups (CH$_2$) of PCL. The absorption band at 1730 cm$^{-1}$ is due to the carbonyl (C=O) vibration of PCL and fumarate. This band is stronger in the VPCLF spectrum because the carbonyl groups of PCL, as well as those of fumaryl chloride, contribute to the absorption band. The weak absorption bands with peak positions at 1240 and 1367 cm$^{-1}$ are due to the C-H rocking vibration of the disubstituted fumarate group while the peak at 1646 cm$^{-1}$ is due to C=C stretching. A relatively strong absorption band with the peak positioned at 1171 cm$^{-1}$, evident in VPCLA and VPCLF spectra, is due to asymmetric coupled vibrations of C-C(=O)-O and O-C-C groups of VPCL. The melting temperatures (T$_m$) of the macromers were determined by DSC and are presented in Figure 3. DSC analysis shows the dependence of the melting temperature T$_g$ as a function of average molecular weight of the macromers. The melting temperature increases progressively by increasing molecular weight. Between Mn=2300 Da and Mn=6800 Da the melting temperature rises from 50.84°C to 53.61°C.

3.2. Photocrosslinking of VPCLF macromers

Photocuring of the VPCL and VPCLF has been performed using two sets of samples by dissolving macromers in NMP (non-reactive solvent) and NVP (reactive solvent) respectively, in presence of a biocompatible UV photo-initiator (Lucirin TPO). Upon UV exposure, polymerization of double bonds leads to formation of linearly grafted PCL. The use of NVP as a crosslinking agent significantly increases the cross-linking rates as it is possible to see from PCA analysis (Table 2). Low reactivity of the system is further confirmed by long induction time and low rate coefficients (k), as compared to the NVP system. High reactivity of the VPCL/NVP system is further corroborated by the lower induction time and higher rate coefficient (k), as it is showed in Table 2. Application of reactive diluent was necessary due to the significantly lower reactivity of synthesized VPCL and VPCLF in comparison with acrylate-functionalized ones. Up to now NVP is preferable to the other small monomers (like acrylic or methacrylic acid) due to the more solubility and biocompatibility of the monomers and degradation products of the system.

3.3. Characterization of VPCLF/NVP network

Although VPCLF has the capability of being crosslinked, its polymerization reaction is very slow and results in a putty-like material after 20 min of irradiation. This behavior is probably due to the lack of enough double bonds or steric hindrance of fumarate double bonds along the VPCLF backbone, which restricts the movement of macro radicals leading to a decrease in maximum double bond conversion. Adding NVP may facilitate the crosslinking reaction, since NVP bridges adjacent VPCLF chains. Using UV irradiation (365 nm) and a biocompatible photo-initiator such as Lucirin TPO, networks were formed from VPCLF macromers and NVP. The network properties were assessed by varying the NVP content from 30 to 50 wt %. After curing for 20 min, the
gel content of the networks was above 85% in all samples. The NVP-containing VPCLF networks absorb significantly more water as it is possible to notice from Figure 4. As a consequence of the hydrophilic character of NVP, the water uptake increases by increasing the NVP content.

3.4. Cell Adhesion to VPCLF/NVP Networks
To assess the suitability of these networks for cell culturing and tissue engineering, initial cell adhesion experiments were performed. The cellular attachment is the first step in evaluating the biocompatibility of hMSC onto the VPCLF material. Figure 5 illustrates the confocal images of hMSCs cellular onto crosslinked material after 1 day of cell culture. Tissue culture polystyrene (TCPS) was used as a positive control (Ctr). It is worth noting that the hMSCs cells adhered well to the VPCLF/NVP networks, presenting a spread morphology and this representative morphology is a positive sign that cells have a good biocompatibility and affinity for the VPCLF/NVP materials. Even though it seems that the cells had a slightly higher tendency to aggregate on the networks with the highest NVP contents, the results indicate good cell adhesion for all the range of VPCLF/NVP networks investigated. Cell proliferation is assessed by alamar blue as shown in Figure 6. For all materials, confluency was reached within 14 days. Our results demonstrated that the materials appeared not to be cytotoxic neither show a negative response to cell adhesion. This confirms that VPCLF/NVP films are suitable substrates for cell culturing.

3.5. Mathematically defined scaffolds
The photochemical and biological features of the developed networks encourage their application in the field of tissue engineering. Accordingly, we studied the possibility of developing porous structures from VPCLF/NVP 50/50 formulations by stereolithography. The VPCLF/NVP resins (also containing 5 wt% Lucirin-TPO, and 0.1 wt% Orange Orasol G) were first analyzed with respect to their photocuring behavior in the stereolithography apparatus. We developed porous VPLCF/NVP network scaffolds with mathematically defined architectures characterized by high pore interconnectivity and specific surface area and they are presented Figure 7. Such features make it an appropriate structures for tissue engineering, since it favors cell-seeding at high densities, also allowing homogeneous cell distribution and flow of nutrients throughout the scaffold. Structural parameters such as porosities, pore sizes and specific surface areas can be evaluated from μCT data. The designed architectural features are preserved and porosity is almost unaffected by the fabrication process as it is possible to notice from Table 3. Early literature suggests a minimum recommended pore size for a scaffold of 100 µm, but recent studies have shown better osteogenesis for implants with pores size higher than 300 µm (Karageorgiou et al., 2005; Hulbert et al., 1970). Relatively larger pores favor direct osteogenesis, since they allow vascularization and high oxygenation, while smaller pores result in osteochondral ossification, although the type of bone ingrowth depends on the biomaterial and the geometry of the pores (Kuboki et al., 2001; Ayers et al., 1999). The porous structures were analyzed by micro-
computed tomography (µCT) and results were reported in Figure 8. As a result of the regularity of the design and the precision of the employed building technique, the histogram shows a narrow pore size distribution for both architectures. The average pore size was 400 µm for the Diamond and 710 µm for the Gyroid. From the µCT data a porosity of 64% and 58% was determined for Gyroid and Diamond structure respectively, while the porosity of the designed architectures was 66% for the Gyroid and 59% for the Diamond. These results clearly show the suitability of the proposed materials to create porous structures with narrow pore size distributions and high pore interconnectivities by stereolithography.

4. Conclusions
In this article a novel approach to synthetize a divinyl fumarate Polycaprolactone that can be used to manufacture tissue engineering scaffolds by stereolithography has been investigated. A non-toxic, Al-based catalyst was used for the polymerization of CL, to avoid the use of potentially cytotoxic Sn (Oct)₂. Hydroxyethyl Vinyl Ether (HEVE) was employed as ROP initiator to introduce a photo-curable vinyl functional group at the beginning of the chain, while fumaric acid was added to the PCL oligomer to obtain a tri-functional UV curable resin. Photopolymerization kinetic of the resulting materials (with and without fumaric group) was studied in both NMP and NVP solution using Lucirin TPO as radical photoinitiator. The best results were obtained when using a reactive solvent, such as NVP. The resins were successfully employed to build complex 3D structures based on Gyroid and Diamond architectures, with high interconnectivity and porosity. The versatility provided by stereolithography technique will allow the fabrication of implants with different porosities, pore sizes and morphology that can mimic the complex architecture of tissue-specific sites. Human Mesenchymal Stem Cells, seeded on scaffolds prepared from VPCLF/NVP resin, were spread on the surface after 24 h and formed a confluent cell layer. Results suggest that VPCLF/NVP macromers is potentially useful as a cross-linkable material for tissue regeneration.
