Hydro-electromechanical modelling of a piezoelectric wave energy converter

E. Renzi

1 Department of Mathematical Sciences, Loughborough University, Leics LE11 3TU, United Kingdom

We investigate the hydro-electromechanical coupled dynamics of a piezoelectric wave energy converter. The converter is made of a flexible bimorph plate, clamped at its ends and forced to motion by incident ocean surface waves. The piezoceramic layers are connected in series and transform the elastic motion of the plate into useful electricity by means of the piezoelectric effect. By using a distributed-parameter analytical approach, we couple the linear piezoelectric constitutive equations for the plate with the potential-flow equations for the surface water waves. The resulting system of governing partial differential equations yields a new hydro-electromechanical dispersion relation, whose complex roots are determined with a numerical approach. The effect of the piezoelectric coupling in the hydro-elastic domain generates a system of short- and long-crested weakly damped progressive waves travelling along the plate. We show that the short-crested flexural wave component gives a dominant contribution to the generated power. We determine the hydro-electromechanical resonant periods of the device, at which the power output is significant.

1. Introduction

The wave energy industry has recently suffered from major pitfalls that highlighted the shortcomings of several concepts to extract energy from the motion of the ocean, see e.g. [1,2]. Among the reasons of such failures are the sheer size and complexity of the proposed devices, and the use of costly design components (e.g. materials, underwater moving parts) to resist the wave action. These factors concur to make the levelised cost of energy (LCOE) of wave energy converters (WECs) not yet competitive against that of fossil fuels [3].
To improve this scenario, new research efforts must focus on innovative ideas, which make use of sleek design and smart materials to generate useful electricity at a much smaller LCOE than that of existing devices. One of such ideas is to use piezoelectric materials, which are able to establish a voltage upon application of an external stress. A piezoelectric WEC (PWEC) exploits the natural cycles of stresses and strains induced by the wave motion to generate an output AC voltage [4]. The estimated power potential of a typical PWEC is in the order of W to kW. This is enough to supply appliances (e.g. LEDs, wireless routers, PCs), ocean buoys and sensors. Despite being less powerful than other WECs (e.g. the nominal capacity of an oscillating wave surge converter is in the order of the hundreds of kW, see [5–7]), PWECs enjoy the significant advantages of being low-maintenance and versatile. For example, they can also be employed to increase wave damping around offshore oil platforms and in combination with nearshore breakwaters [4].

Although ambient power harvesting through piezoelectricity has a long and honourable history [8], its application to ocean energy conversion has been proposed only in the past few years. Novel PWEC concepts include cantilevered beams [9,10] and piezoelectric buoys [11]. So far, such devices have been studied with rather simplified mathematical models, in which the effect of the piezoelectric layers on the dynamic response of the system was neglected. The bending force resulting from the action of the waves on the structure was plugged separately into the electric circuit equations to estimate the voltage on the piezoelectric layers [9–11]. With that simplified approach, the hydro-electromechanical problem was in fact uncoupled into two separate wave-structure and electric problems. Such an approximate analysis is useful to obtain a preliminary estimate of the extracted power, but cannot be trusted to provide accurate results. Indeed, in reality the dynamics of waves, structural elasticity and piezoelectricity are inherently coupled in a PWEC, and so the development of a hydro-electromechanical model is fundamental to provide an accurate analysis of the system.

In this paper, we analyse the coupled hydro-electromechanical dynamics of a piezoelectric plate WEC. The idea of using a flexible plate to extract energy from the waves was first introduced by Koola and Ibragimov [12], though they did not model any power take-off mechanism, and is inspired by nature. It is long known that spreading a thin film of oil on the sea surface has the effect of calming troubled waters. For example, this practice was used by ancient sailors, as described by Benjamin Franklin [13]. Later, Lamb showed that the tension variations at the oil-water interface ”produce an alternating tangential drag on the water, with a consequent increase in the rate of dissipation of energy” [14]. Similarly, a piezoelectric plate WEC can extract energy from the ambient wave motion by converting tension variations at the plate-water interface into a voltage, thanks to the piezoelectric effect. This, in turn, exerts a damping action on the waves. Piezoelectric plates have already been considered for the task of extracting energy from currents. For example, Doaré and Michelin [15,16] developed a coupled model of energy extraction from piezoelectric flags fluttering in an axial flow. However, to the best of our knowledge, no coupled models of wave energy extraction from piezoelectric plates have been developed yet.

We consider the power generation by a bimorph piezoelectric plate in ocean surface waves of varying frequency. We derive a novel hydro-electromechanical dispersion relation for the flexural waves propagating on the plate. The piezoelectric coupling in the hydro-elastic domain generates a system of short- and long-crested weakly damped progressive waves travelling along the plate. We show that the short-crested flexural wave component gives a dominant contribution to the generated power. We determine new hydro-electromechanical resonant periods at which the power output of the device is significant.

This paper is organised as follows. First, we introduce the governing equations of the coupled system by using a distributed-parameter approach for the piezoelectric plate and a potential-flow theory for the waves (Section 2). Then, we solve the coupled system of partial differential equations by means of domain decomposition and the method of matching potentials (Section 3). After that, we analyse the mechanism of wave power extraction by the device (Section 4) and discuss the behaviour of a typical configuration of the piezoelectric plate WEC (Section 5). Conclusions and suggestions for further work are finally presented (see Section 6).
Figure 1. Geometry of the system in physical variables. The local reference system on the plate is \((X', Y', Z')\) and the global coordinate system is \((x', y', z')\). The plate is long \(2L'\) and is clamped at both ends at a depth \(d'\) in an ocean of constant depth \(h'\).

2. Governing equations

Referring to figure 1, define a global coordinate system \((x', y', z')\), with the \(z'\)-axis pointing upwards from the undisturbed water level \(z' = 0\). The \(x'\)-axis is directed along the direction of propagation of incoming surface waves of amplitude \(A'\) and angular frequency \(\omega'\). Variables with primes denote physical quantities. The bottom of the ocean is located at a constant depth \(z' = -h'\) and the piezoelectric converter is a flexible plate, clamped at both ends at \((x', z') = (\pm L', -d')\).

As is usual in structural dynamics [17], we introduce a local reference system on the plate, with \((X', Y', Z') = (x', -y', -z' - d')\), so that the local \(Z'\) axis points downwards (see again figure 1).

In this section, we shall first derive a distributed-parameter model for the governing equations of the piezoelectric plate in the local reference system. Then we shall couple the model equations of the piezoelectric plate with those of the surface waves, based on a potential-flow theory, in the global reference system.

(a) Distributed-parameter modelling of the piezoelectric plate

Consider a flexible plate whose width in the transverse \(Y'\) direction is much greater than its length \(2L'\) along the \(X'\) axis. Hence, the deformations of the plate will be modelled as purely two-dimensional, i.e. \(\partial/\partial Y' = 0\). Consider a bimorph configuration of the plate, in which piezoelectric layers are perfectly bonded to both faces of a flexible substrate, with opposite polarities in the \(Z'\) direction, as shown in figure 2. Such a symmetric bimorph configuration is also used in the design of cantilevered piezoelectric energy harvesters from ambient vibrations, see [8]. Electrodes of negligible thickness cover the top and the bottom faces of each piezoelectric layer and ensure that a potential difference is established across them. We assume that the deformations are small and that the behaviour of the structure is linear elastic. The piezoelectric layers are homogeneous and have thickness \(d_{p}\), Young’s modulus \(E_{p}\) (in \(N/m^2\)) and Poisson’s ratio \(\nu_{p}\). The piezoelectric layers are made of discrete piezoelectric patches, each of length \(dX' \ll L'\). The patches are arranged one after another to cover both sides of the substrate [8,15]. The elastic substrate is homogeneous and has thickness \(d_{0}\), Young’s modulus \(E_{0}\) and Poisson’s ratio \(\nu_{0}\). From now on, primes will be dropped for simplicity in this subsection. Because the system is homogeneous, the vertical displacement \(W(X, t)\), the stresses \(\sigma_{ij}(X, Z, t)\), with \(i, j = X, Y, Z\), the strains \(\epsilon_{ij}(X, Z, t)\) and the voltage \(V(X, t)\) are continuous along the plate. Hence, the converter can be modelled as a uniform composite plate based on the Kirchhoff plate theory [17].

Consider the cylindrical bending of a plate element of unit width and length \(dX \ll L\), under the action of a vertical surface load \(\tilde{q}(X, t)\) (in \(N/m^2\)). The equation of motion of the plate element
Figure 2. Geometry of the piezoelectric plate and detail of the bimorph configuration for an element of length \( dX' \ll L' \), corresponding to the length of a piezoelectric patch. The bold vertical arrows indicate the poling direction of the piezoelectric layers (from negative to positive pole). Electrodes of negligible thickness cover both faces of each piezoelectric patch. Each pair of piezoelectric patches are shunted with an external resistance \( 1/\Gamma' \), thus powering a resistive circuit.

in the local coordinate system of figure 2 is

\[
\frac{\partial^2 M_{XX}}{\partial X^2} - I_b \frac{\partial^2 W}{\partial t^2} = -\ddot{q},
\]  

(2.1)

see [17], where

\[
M_{XX} = \int_{-d_b/2}^{d_b/2} \sigma_{XX} Z \, dZ
\]

(2.2)

is the internal bending moment per unit width (in N), \( d_b = d_0 + 2d_p \ll L \) is the total thickness of the bimorph and

\[
I_b = \int_{-d_b/2}^{d_b/2} \rho(Z) \, dZ = \rho_0 d_0 + 2\rho_p d_p
\]

(2.3)

is the surface density of the bimorph (in kg/m²). In (2.3), \( \rho_p \) is the density of the piezoelectric layers and \( \rho_0 \) is the density of the substrate. We consider isotropic materials, so that the constitutive linear elastic equation for the substrate is

\[
\sigma_{XX} = \frac{E_0}{1 - \nu_0^2} \epsilon_{XX}.
\]

(2.4)

Now define the 1-, 2-, 3-axes of piezoelectricity and couple them with the material X-, Y- and Z-directions, respectively. The piezoelectric constitutive equations for the layers are

\[
\sigma_{XX} = \frac{E_p}{1 - \nu_p^2} \epsilon_{XX} - \frac{E_p d_{31}}{1 - \nu_p} E_3,
\]

(2.5)

\[
D_3 = \frac{E_p d_{31}}{1 - \nu_p} \epsilon_{XX} + \epsilon S E_3.
\]

(2.6)

In the latter, \( E_3(X,t) \) is the vertical component of the electric field \( E \) (in V/m), \( D_3(X,t) \) is the vertical component of the electric displacement \( D \) (in C/m²), \( \epsilon S \) is the permittivity of the piezoceramic at constant strain (in F/m) and \( d_{31} \) is the piezoelectric coupling constant (in m/V), see [8]. Since the electrodes are aligned along the horizontal X-direction, the electric field and electric displacement are both aligned along the vertical Z-direction [19]. Note that the sign of \( d_{31} \) is opposite for the top \((d_{31} < 0)\) and bottom \((d_{31} > 0)\) piezoelectric layers, according to the relevant poling directions (see again figure 2).
In the absence of axial displacements, $\epsilon_{XX} = -Z \partial^2 W / \partial X^2$. Now, substitute the latter expression into (2.4)–(2.5). Then substitute the resulting equations into (2.2) and integrate over the thickness of the plate to get

$$M_{XX} = -B \frac{\partial^2 W}{\partial X^2} - \frac{E_p |d_{31}|}{1 - \nu_p} (d_0 + d_p) E_3 d_p,$$

(2.7)

where

$$B = \frac{E_0 d_0^3}{12(1 - \nu_0^2)} + \frac{2E_p d_p}{1 - \nu_p} \left( \frac{d_0^3}{4} + \frac{d_0 d_p}{2} + \frac{d_p^3}{3} \right)$$

(2.8)

is the flexural rigidity of the bimorph. Since the piezoelectric layers are connected in series (see again figure 2), the voltage across the electrodes of each piezoceramic layer is the same. For the top layer, $V_p = -\int E \cdot dX = -E_3 d_p$, so that the total voltage is $V(X, t) = 2V_p = -2E_3 d_p$, see [19]. Substitution of the latter expression into (2.7) yields the coupled electro-mechanical equation

$$M_{XX} = -B \frac{\partial^2 W}{\partial X^2} + \theta V,$$

(2.9)

where

$$\theta = \frac{E_p |d_{31}|}{1 - \nu_p} \frac{d_0 + d_p}{2}$$

is a piezoelectric coupling factor (in N/V or, equally, in C/m).

Now, we need to pair (2.9) with the electrical circuit equations, which describe the power take-off (PTO) mechanism of the converter. Following a common practice in modelling vibration-based energy harvesters, we model the PTO for each elementary stripe of length $dX$ by shunting the piezoelectric patches with a resistance [15]. Hence, each piezoelectric pair powers a resistive circuit (see again figure 2). As a result of the Gauss law, the electric charge on the piezoelectric patches with a resistance [19] is the load of the circuit (in $S^{-1}$). Differentiating (2.10) over the elementary area $dA$, using the second piezoelectric relation (2.6) for $D_3$ and substituting $E_3 = -V/(2d_p)$ gives

$$Q = \frac{E_p d_{31}}{1 - \nu_p} \epsilon_{XX} - CV.$$

(2.11)

In the latter, $Q(X, t) = d\theta / dA$ is the charge per unit area of the piezoelectric layer and $C = \epsilon^2/(2d_p)$ is the electrical surface capacitance (in F/m²), see [19]. Finally, substitution of $\epsilon_{XX} = -Z \partial^2 W / \partial X^2$ into (2.11) and further integration along $Z$ over any of the piezoelectric patches yields the sought electromechanical equation

$$Q = -\theta \frac{\partial^2 W}{\partial X^2} - CV.$$

(2.12)

The latter shows that each piezoelectric layer is acting as a parallel-plate capacitor connected in series with the resistance [19]. Now note that our system is still underdetermined, as we have four unknowns ($Q, V, W, M_{XX}$), but only three equations, namely (2.1), (2.9) and (2.12). One last equation is needed to close the system, and that is indeed Ohm’s resistive law: $\partial \theta / \partial t = \Gamma V$, where $\Gamma = 1/R$ is the conductance and $R$ is the resistive load of the circuit (in $S^{-1}$). Differentiating
Ohm’s law over the elementary area dA, in which $V$ is constant, we get

$$\frac{\partial Q}{\partial t} = GV,$$  

(2.13)

where $G = dI/dA$ is the surface conductance (in S/m²). Expressions (2.1), (2.9), (2.12) and (2.13) are the sought electromechanical equations which govern the dynamics of the bimorph. They are similar to the continuous form of the discrete equations derived by [15] and to the system obtained in the Laplace space by [20].

The governing differential equations must be accompanied by appropriate boundary conditions. Since the plate is clamped at both ends, we have

$$W(\pm L, t) = \frac{\partial W(X, t)}{\partial X} \bigg|_{X = \pm L} = 0.$$  

(2.14)

If now the plate is immersed in water waves, the dynamic surface load $\tilde{q}(X, t)$ of (2.1) is precisely the pressure forcing applied by the wave field on the plate. Hence, the electromechanical equations need to be coupled with a hydrodynamic system, which is derived in the next subsection.

(b) Potential-flow modelling of the ocean surface waves

In this subsection, we derive the governing equations of the hydrodynamic problem in the global reference system $(x', y', z')$. Use of primes to denote physical quantities is reintroduced from now on. Accordingly, unprimed variables will denote non-dimensional values. We assume that the clamps at the end of the plate do not have any significant effect on the wave field. Within the framework of a linearised potential flow theory, the fluid is inviscid and incompressible and the flow is irrotational. Hence there exists a velocity potential $\Phi'(x', z', t')$ that satisfies the Laplace equation

$$\nabla'^2 \Phi' = 0$$  

(2.15)

in the fluid domain, the kinematic-dynamic boundary condition on the free surface

$$\frac{\partial^2 \Phi'}{\partial t'^2} + g \frac{\partial \Phi'}{\partial z'} = 0, \quad z' = 0,$$  

(2.16)

where $g$ is the acceleration due to gravity, the Bernoulli equation

$$gz' + \frac{P'}{\rho} + \frac{\partial \Phi'}{\partial t'} = 0$$  

(2.17)

in the fluid domain, where $P'$ is the total pressure and $\rho$ is the density of the ocean, and the no-flux condition at the bottom,

$$\frac{\partial \Phi'}{\partial z'} = 0, \quad z' = -h'.$$  

(2.18)

Finally, $\Phi'$ also needs to satisfy a kinematic condition on the surface of the plate. Let $\lambda'$ be the characteristic wavelength of the incident waves. Assume that such wavelength is comparable to the total length of the device, $\lambda'/(2L') = O(1)$. Since the total thickness of the plate $d_b' \ll 2L' \sim \lambda'$, we can apply the thin-plate hypothesis and consider the thickness of the plate to be immaterial in solving the potential-flow problem, see [5]. This yields the kinematic condition

$$\frac{\partial W'}{\partial t'} = \frac{\partial \Phi'}{\partial z'}, \quad |x'| \leq L', \quad z' = d' \pm \delta', \quad \delta' \to 0.$$  

(2.19)
3. Solution of the coupled system

We are now in a position to couple the electro-mechanical and the hydrodynamic problems. With this aim, first replace the surface load in (2.1) with the pressure forcing of the waves

\[
q'(X', t') = P'(X', -d' + \delta', t') - P'(X', -d' - \delta', t') = P_{1}' - P_{-}', \quad \delta' \to 0.
\]  

(3.1)

Then substitute the electro-mechanical equations (2.9) and (2.12) into the equation of motion (2.1) and rewrite the result in the global reference system \((x', z')\) to get

\[
\left( B' + \frac{\theta'^2}{C'} \right) \frac{\partial^4 W'}{\partial x'^4} + \left( B' + \frac{\theta'^2}{C'} \right) \frac{\partial^2 W'}{\partial t'^2} - \frac{\theta'}{C'} \frac{\partial^2 Q'}{\partial x'^2} = \Delta P'.
\]

(3.2)

In the latter, \(W'\) is now defined positive upwards and \(\Delta P'(x', t') = P_{1}' - P_{-}'\) is the pressure jump across the plate in the \(z'\)-direction. Hence, (3.2) is a coupled hydro-electromechanical equation.

The electromechanical equation (2.12) and the circuit equation (2.13) in the global reference system are

\[
Q' = C' V' + \theta' \frac{\partial^2 W'}{\partial x'^2}
\]

(3.3)

and

\[
V' + \frac{1}{G} \frac{\partial Q'}{\partial t'} = 0,
\]

(3.4)

respectively (note that \(E'\) and \(V'\) change sign when expressed in the global coordinates).

Let us now introduce the following non-dimensional variables:

\[
(x', y', z', h', d') = L'(x, y, z, h, d), \quad t' = \sqrt{\frac{L'}{g}} t, \quad \Phi' = \sqrt{gL'A'} \Phi, \quad P' = \rho g A' P,
\]

\[
Q' = A' \sqrt{\frac{g L' C'}{L}} Q, \quad V' = A' \sqrt{\frac{g L' B'}{L C'}} V, \quad W' = A' W.
\]

(3.5)

Upon substitution of (3.5), the coupled hydro-electromechanical equation of motion (3.2) becomes

\[
\beta (1 + \alpha^2) W_{xxxx} + W_{tt} - \frac{\alpha}{\gamma} Q_{xx} = r \Delta P.
\]

(3.6)

In the latter, subscripts denote differentiation with respect to the relevant variable and

\[
\alpha = \frac{\theta'}{\sqrt{B' C'}}
\]

(3.7)

is a non-dimensional piezoelectric coupling parameter,

\[
\beta = \frac{B'}{L'^3 H' g}
\]

(3.8)

is a non-dimensional stiffness,

\[
r = \frac{\rho L'}{H'}
\]

(3.9)

is a surface density ratio and finally \(\gamma = 1/\sqrt{\beta}\). Analogously, the non-dimensional forms of the electromechanical equation (3.3) and the circuit equation (3.4) are, respectively,

\[
Q = V + \frac{\alpha}{\gamma} W_{xx},
\]

(3.10)

\[
V + \xi Q_t = 0,
\]

(3.11)

where

\[
\xi = \frac{C'}{g} \sqrt{\frac{g}{L'}}
\]

(3.12)
is a non-dimensional resistive term. Finally, the non-dimensional kinematic conditions at the ends of the plate (2.14) become
\[ W(\pm 1, t) = W_x(x, t)|_{z=\pm 1} = 0. \] (3.13)

Non-dimensionalisation of the hydrodynamic equations (2.15)–(2.19) according to (3.5) yields, respectively,
\[ \nabla^2 \Phi = 0 \] (3.14)
for the Laplace equation in the fluid domain,
\[ \Phi_{tt} + \Phi_z = 0, \quad z = 0, \] (3.15)
for the kinematic-dynamic boundary condition on the free surface,
\[ \frac{L'}{A'} z + P + \Phi_t = 0, \] (3.16)
for the Bernoulli equation,
\[ \Phi_z = 0, \quad z = -h, \] (3.17)
for the bottom boundary condition and finally
\[ W_t = \Phi_z, \quad |x| \leq 1, z = -d \pm \delta, \quad \delta \to 0, \] (3.18)
for the kinematic boundary condition on the plate.

Since the wave forcing is harmonic with frequency \( \omega \), time can be factored out by introducing the spatial variables
\[ \{ \Phi(x, z, t), P(x, z, t), W(x, t), V(x, t) \} = \Re \left\{ |\phi(x, z), p(x, z), w(x), v(x)| e^{-i\omega t} \right\}, \] (3.19)
where \( i \) is the imaginary unit. In the following, the real part operator \( \Re \) will be omitted for the sake of brevity. We shall now write the coupled boundary-value problem in terms of the spatial potential \( \phi \) only. First, substitute (3.19) into the hydrodynamic equations (3.14), (3.15) and (3.17) to get the following system,
\[ \nabla^2 \phi = 0, \quad \text{in fluid domain} \] (3.20)
\[ \phi_z - \omega^2 \phi = 0, \quad z = 0, \] (3.21)
\[ \phi_z = 0, \quad z = -h. \] (3.22)

Second, substitute the factorisation (3.19) into the electro-mechanical equations (3.6), (3.10) and the Bernoulli equation (3.16). Then couple them all together to get the following dynamic boundary condition on the plate,
\[ \beta \left( 1 + \frac{\alpha^2 \omega \xi}{1 + \omega \xi} \right) \phi_{xxxxz} - \omega^2 \phi_z = \omega^2 r \Delta \phi, \quad |x| < 1, z = -d \pm \delta, \quad \delta \to 0, \] (3.23)
where, accordingly, \( \Delta \phi(x) \) is the jump of the spatial potential across the plate along the \( z \)-direction. Finally, substitute (3.19) into the end conditions (3.13) and the kinematic equation (3.18). Again, couple the equations together to obtain
\[ \phi_z = \phi_{xz} = 0, \quad x = \pm 1, z = -d \pm \delta, \quad \delta \to 0. \] (3.24)

The system (3.20)–(3.24) is now expressed in terms of the spatial potential \( \phi \) only and will be solved with the method of matching potentials [21]. Note that, in the short-circuit limit \( \xi \to 0 \), the second term inside the brackets at the left-hand side of (3.23) vanishes. Within this limit, the fifth derivative of the velocity potential in (3.23) is multiplied only by the non-dimensional stiffness \( \beta \) and the resulting boundary-value problem is equivalent to that of a submerged elastic plate without power extraction [22–25], as expected. Indeed, the complex coefficient \( \alpha^2 \omega \xi/(i + \omega \xi) \) in (3.23) is a dissipative term which models the extraction of energy from the system by means of the resistive circuits of figure 2.
The boundary-value problem (3.20)–(3.24) is now well-posed, as it consists of the governing partial differential equation (3.20) and appropriate conditions at each of the physical boundaries of the system. To find the solution, we follow [24,27] and split the fluid domain into four different areas, as shown in figure 3. The matching conditions at the common boundaries of the four domains are

\[
\phi_2 \big|_{z} = \phi_3 \big|_{z}, \quad |x| < 1, \quad z = -d, \tag{3.25}
\]

\[
\phi_1 = \phi_2, \quad \phi_{1x} = \phi_{2x}, \quad x = -1, \quad z \in (-d, 0), \tag{3.26}
\]

\[
\phi_1 = \phi_3, \quad \phi_{1x} = \phi_{3x}, \quad x = -1, \quad z \in (-h, -d), \tag{3.27}
\]

\[
\phi_2 = \phi_4, \quad \phi_{2x} = \phi_{4x}, \quad x = 1, \quad z \in (-d, 0), \tag{3.28}
\]

\[
\phi_3 = \phi_4, \quad \phi_{3x} = \phi_{4x}, \quad x = 1, \quad z \in (-h, -d), \tag{3.29}
\]

where the \(\phi_i\) denote the potential \(\phi\) in each area \(i = 1, 2, 3, 4\). We also require that the scattered potentials in the open ocean areas 1 and 4 are outgoing in the far field [21]. We shall now solve the boundary-value problem separately in each region and then match the potentials via (3.25)–(3.29).

(a) Regions 1 and 4

The boundary-value problem for \(\phi_1(x, z)\) is simply (3.20)–(3.22). The solution is the well-known superimposition of incident, reflected (left-going) and evanescent waves [21],

\[
\phi_1(x, z) = \frac{1}{\omega} \frac{\cosh[k(z + h)]}{\cosh(kh)} e^{ikx} \sum_{n=0}^{\infty} R_n e^{-i\kappa_n x} Z_n(z). \tag{3.30}
\]

In the latter, the \(R_n\) are unknown complex coefficients, while \(\kappa_0 = k\) and \(\kappa_n = ik_n\) are the solutions of the dispersion relation

\[
\omega^2 = k \tanh(kh); \quad \omega^2 = -k_n \tan(k_n h). \tag{3.31}
\]

Still in (3.30), the \(Z_n\) are the orthonormal functions

\[
Z_n(z) = \frac{\sqrt{2} \cosh[k_n(z + h)]}{\left(h + \omega^{-2} \sinh^2(k_n h)\right)^{1/2}}. \tag{3.32}
\]

The latter satisfy \(\int_{-h}^{0} Z_n Z_m \, dz = \delta_{nm}\), where \(\delta_{nm}\) is the Kronecker delta, see [5,21].
The latter expression is an even complex function of the hydro-electromechanical dispersion relation (3.37) for a typical system configuration. In this case, \( \sigma \) to real roots, say \( \sigma \pm s \), solutions to the calculation of the unknown parameters \( R \) in the complex plane, discarding their repetitions in the 2nd and 3rd quadrants. Before proceeding with the calculation of the unknown parameters \( R \), see (3.35)–(3.36), the \( R \) matches the dispersion relation of a submerged elastic plate studied by Hassan and Meylan [24]. Within this limit, (3.37) is known to admit two complex roots, say \( \sigma_{1} \) and \( \sigma_{2} \), two positive real roots, say \( \sigma_{0} \) and \( \sigma_{1} \), and an infinite number of positive imaginary roots \( \sigma_{n} \), \( n = 2, 3, \ldots \), for typical plate parameters [24]. Now, the presence of the complex piezoelectric term proportional to \( \xi \) in (3.37) changes the location of the roots of the dispersion relation in the complex plane, with respect to the short-circuit scenario. Figure 4 shows the location of the complex roots of the hydro-electromechanical dispersion relation (3.37) for a typical system configuration. In this case, \( \xi \rightarrow 0 \), the hydro-electromechanical equation (3.37) coincides with the dispersion relation of a submerged elastic plate studied by Hassan and Meylan [24]. Within this limit, (3.37) is known to admit two complex roots, say \( \sigma_{-2} \) and \( \sigma_{-1} \), two positive real roots, say \( \sigma_{0} \) and \( \sigma_{1} \), and an infinite number of positive imaginary roots \( \sigma_{n} \), \( n = 2, 3, \ldots \), for typical plate parameters [24]. Now, the presence of the complex piezoelectric term proportional to \( \xi \) in (3.37) changes the location of the roots of the dispersion relation in the complex plane, with respect to the short-circuit scenario. Figure 4 shows the location of the complex roots of the hydro-electromechanical dispersion relation (3.37) for a typical system configuration. In this case, \( \xi \rightarrow 0 \), the hydro-electromechanical equation (3.37) coincides with the dispersion relation of a submerged elastic plate studied by Hassan and Meylan [24]. Within this limit, (3.37) is known to admit two complex roots, say \( \sigma_{-2} \) and \( \sigma_{-1} \), two positive real roots, say \( \sigma_{0} \) and \( \sigma_{1} \), and an infinite number of positive imaginary roots \( \sigma_{n} \), \( n = 2, 3, \ldots \), for typical plate parameters [24]. Now, the presence of the complex piezoelectric term proportional to \( \xi \) in (3.37) changes the location of the roots of the dispersion relation in the complex plane, with respect to the short-circuit scenario. Figure 4 shows the location of the complex roots of the hydro-electromechanical dispersion relation (3.37) for a typical system configuration.
Figure 4. Location of the first 11 eigenvalues of the hydro-electromechanical dispersion relation $F(\sigma_n) = 0$ in the complex $\sigma_n$ plane, see (3.37). The solid blue lines identify the contours $\Re\{F\} = 0$, while the dashed red lines correspond to the contours $\Im\{F\} = 0$. The parameters are $\alpha = 0.21$, $\beta = 3.8 \times 10^{-4}$ and $\xi = 1$.
Table 1. Numerical values of the complex eigenvalues \( \sigma_n \), solutions of the dispersion relation (3.37), represented in figure 4. The numerical tolerance of the Newton-Raphson scheme is \( \epsilon = 10^{-9} \).

</table>

In the latter, the wavenumbers \( \sigma_0 \) and \( \sigma_1 \) have a small imaginary part (see table 1), which means that their horizontal decay is weaker than that of the porous plate case. This scenario corresponds to waves that traverse the device and trigger the piezoelectric effect on the plate, which in turn damps the wave height. Furthermore, note from table 1 that \( \Re \{ \sigma_1 \} \gg \Re \{ \sigma_0 \} \). Since the real part of the wavenumber is related to the propagating part of the perturbation, the latter inequality means that \( \sigma_1 \) and \( \sigma_0 \) correspond, respectively, to short- and long-crested waves (see again figure 4). This does not happen in the flexible plate case of [24] and in the porous plate case of [27], where the two wavenumbers are comparable. Therefore, the occurrence of a coupled system of short- and long-crested weakly damped progressive waves that propagate in the plate region is a distinctive feature of the submerged piezoelectric plate. We will show later that the short-crested wave component is responsible for the resonant enhancement of the power generated by the device, see Section 5.

(d) Numerical solution

Having solved the dispersion relation (3.37), we are now in a position to find the numerical values of the amplitude coefficients \( A_n, B_n, R_n \) and \( T_n \). First, substitute the solutions \( \phi_1 (3.30), \phi_2 \) and \( \phi_3 (3.34) \) into the first conditions of both (3.26) and (3.27). Then multiply both equations by \( Z_m(z) \), \( m = 0, 1, ... \), integrate them along \( z \) over the respective domains and finally sum the results to obtain

\[
R_m = \frac{i}{\omega} e^{-i(k+k_m)} a_m \delta_{0n} + \sum_{n=-N}^{N} \left[ A_n e^{-i(\sigma_n + k_m)} + B_n e^{i(\sigma_n - k_m)} \right] b_{mn}, \quad m = 0, 1, ..., N. \tag{3.38}
\]

In the latter, the orthogonality of the vertical modes \( Z_m(z) \) has been exploited and the sum has been truncated to a finite value \( n = N \) for numerical evaluation. Still in (3.38),

\[
a_m = \int_{-h}^{0} \frac{\cosh[k(z + h)]}{\cosh(kh)} Z_m(z) \, dz, \tag{3.39}
\]

\[
b_{mn} = \int_{-d}^{0} \psi^{(2)}_{n}(z) Z_m(z) \, dz + \int_{-d}^{-h} \psi^{(3)}_{n}(z) Z_m(z) \, dz. \tag{3.40}
\]
are complex coefficients. Using the same procedure to match the fluxes (second conditions of both 3.26 and 3.27) gives

\[ \sum_{n=-2}^{N} \left[ A_n e^{-i\sigma_n (\sigma_n + \kappa_m)} - B_n e^{i\sigma_n (\sigma_n - \kappa_m)} \right] b_{mn} = -\frac{i}{\omega} (k + \kappa_m) e^{-ik} A_m \delta_{0n}, \quad m = 0, 1, \ldots, N. \]  

(3.41)

Finally, matching potentials and fluxes at the common boundary between regions 3 and 4 (see equations 3.28 and 3.29) gives

\[ T_m = \sum_{n=-2}^{N} \left[ A_n e^{i(\sigma_n - \kappa_m)} + B_n e^{-i(\sigma_n + \kappa_m)} \right] b_{mn}, \quad m = 0, 1, \ldots, N, \]  

(3.42)

\[ \sum_{n=-2}^{N} \left[ A_n e^{i\sigma_n (\sigma_n - \kappa_m)} - B_n e^{-i\sigma_n (\sigma_n + \kappa_m)} \right] b_{mn} = 0, \quad m = 0, 1, \ldots, N. \]  

(3.43)

Expressions (3.41) and (3.43) are \( 2(N + 1) \) equations in \( 2(N + 3) \) unknowns, namely the \( A_n \) and \( B_n, n = -2, -1, \ldots, N \). Hence we need four additional equations to close the system. These are readily provided by the clamping conditions on the plate (3.24), which we have not used yet. Substitution of either \( \phi_2 \) or \( \phi_3 \) into (3.24) gives the following four equations:

\[ \sum_{n=-2}^{N} \left( A_n e^{-i\sigma_n} + B_n e^{i\sigma_n} \right) F_n = 0, \]  

(3.44)

\[ \sum_{n=-2}^{N} \left( A_n e^{i\sigma_n} + B_n e^{-i\sigma_n} \right) F_n = 0, \]  

(3.45)

\[ \sum_{n=-2}^{N} \left( A_n \sigma_n e^{-i\sigma_n} - B_n \sigma_n e^{i\sigma_n} \right) F_n = 0, \]  

(3.46)

\[ \sum_{n=-2}^{N} \left( A_n \sigma_n e^{i\sigma_n} - B_n \sigma_n e^{-i\sigma_n} \right) F_n = 0. \]  

(3.47)

where

\[ F_n = \left[ \omega^2 \cosh(\sigma_n d) - \sigma_n \sinh(\sigma_n d) \right] \sigma_n \sinh[\sigma_n (h - d)]. \]  

(3.48)

The system (3.41),(3.43)–(3.48) can now be solved numerically for the \( A_n \) and \( B_n \) with a suitable choice of \( N \). Details on the numerical convergence of the system are given in Appendix A. Once the \( A_n \) and \( B_n \) are known, the \( R_n \) and \( T_n \) can be found directly with (3.38) and (3.42), respectively.

4. Plate motion and wave power extraction

Having solved numerically the boundary-value problem for the potential, we can easily determine all the remaining quantities of engineering interest. First, define the free-surface elevation \( \zeta' = \zeta'(x', t') = A' \zeta(x, t) \), so that \( \zeta' = \Phi_{z}|_{z=0} \) see [21]. Then, factor time out by defining \( \zeta(x, t) = \Re \{ \eta(x) e^{-i\omega t} \} \). Hence,

\[ \eta_i(x) = \frac{i}{\omega} \phi_i(x, z)|_{z=0}, \quad i = 1, 2, 4, \]  

(4.1)

is the spatial component of the free-surface elevation in the region \( i = 1, 2, 4 \). Substituting the relevant forms for the potentials (3.30)–(3.33) into (4.1), we obtain the reflection coefficient in
region 1,

\[ R = \frac{i}{\omega} R_0 \frac{\sqrt{2} k \sinh(\omega)}{h + \omega^2 \sinh^2(\omega)} \]  

(4.2)

and the transmission coefficient in region 4,

\[ T = \frac{i}{\omega} T_0 \frac{\sqrt{2} k \sinh(\omega)}{h + \omega^2 \sinh^2(\omega)} \]  

(4.3)

see [21]. Combining (3.18), (3.19) and (3.34), we obtain the spatial displacement of the plate,

\[ w(x) = \frac{i}{\omega} \sum_{n=-2}^{N} \left( A_n e^{i \sigma_n x} + B_n e^{-i \sigma_n x} \right) F_n. \]  

(4.4)

Concerning the energy budget of the device, the rate of mechanical energy flux is \( W_m' = W_p' - W_{cl}' - P' \), where \( W_p' \) is the rate of work of the fluid force on the plate, \( W_{cl}' \) is the rate of electrical energy flux and \( P' \) is the electric power available in the output system per unit width (see [16]). The latter is given by

\[ P' = \frac{(A' g)^2 L' C'}{G' L} P, \]  

(4.5)

Using Ohm’s law (2.13) and integrating over the length of the device and over a period \( T' = 2\pi/\omega' \), we obtain the average power

\[ \bar{P} = \frac{1}{T} \int_0^T Q_t(x, t) \, dt \]  

(4.7)

in W/m, where

\[ \bar{P} = \frac{\omega^2}{2} \int_{-1}^{1} \left[ \frac{\alpha}{\gamma(1 - \omega^2)} \right]^2 \, dx, \]  

(4.8)

for the non-dimensional average power per unit width of the device. For a resistive circuit in permanent periodic regime, Michelin & Doaré [16] have shown that \( \bar{W}_p = \bar{P} \).

5. Discussion

In this section, we analyse the dynamics of wave power extraction for a typical plate configuration. As in Section 3, the length of the plate is \( 2L' = 20 \text{ m} \), the water depth is \( h' = 10 \text{ m} \) and the submergence of the plate is \( d' = 2 \text{ m} \). The rubber layer has thickness \( d_0' = 0.01 \text{ m} \) and each of the piezoelectric layers have thickness \( d_p' = 1.1 \times 10^{-4} \text{ m} \). The system parameters for silicone rubber (substrate) and PVDF (piezoelectric layers) are \( \alpha = 0.21, \beta = 3.8 \times 10^{-4} \) and \( \xi = 1 \).

(a) Piezoelectric plate dynamics and wave power extraction

Figure 5 shows a snapshot of the system with the displacements \( w'(x', t') \) of the flexible piezoelectric plate and the free-surface elevation \( \zeta(x', t') \). The ocean surface waves have amplitude \( A' = 1 \text{ m} \) and period \( T' = 5 \text{s} \), corresponding to a wavelength \( \lambda' = 36.58 \text{ m} \). Note that the free surface matches seamlessly across the regions defined in Section 3 and that the clamping conditions on the plate, i.e. absence of displacements and rotations, are correctly satisfied by
Figure 5. Snapshot of the free-surface elevation $\zeta'(x',t')$ and plate displacements $u'(x',t')$ at time $t' = T'$.

Parameters are: $A' = 1\,\text{m}$, $T' = 5\,\text{s}$, $\alpha = 0.21$, $\beta = 3.8 \times 10^{-4}$ and $\xi = 1$. The first 12 flexural plate modes have been considered.

The numerical solution. On the plate, weakly damped progressive waves superimpose to create short-crested oscillations of wavelength $\lambda'_1 = 2\pi L'/R\{\sigma_1\}$, slowly modulated by a long-crested oscillation of wavelength $\lambda'_0 = 2\pi L'/R\{\sigma_0\}$. In this example, $\lambda'_1 = 2.79\,\text{m}$ and $\lambda'_0 = 36.55\,\text{m}$, which is very close to the wavelength $\lambda'$ of the incident wave. The physical picture is hence clear. Due to the coupled hydro-electromechanical effect, the incident wave is able to excite a coupled system of long- and short-crested flexural waves. The long-crested component propagates essentially with the same wavelength and phase speed $c'_0 = \lambda'_0/T' = 7.31\,\text{m/s}$ of the incoming wave. On the other hand, the short-crested waves travel at a much smaller wavelength and speed $c'_1 = 0.56\,\text{m/s}$ than that of the forcing waves.

While the 0th-mode long-crested component is the direct effect of the incident wave forcing, the nature of the 1st-mode short-crested wave is more puzzling. To gain a better physical insight into it, let us consider again the hydro-electromechanical dispersion relation and derive its asymptotic form for short waves. The short-wave limit of (3.37) when $R\{\sigma_n\} \gg 1$ yields the following approximation for the 1st-mode wavenumber,

$$\sigma_1 \sim \left[ \frac{2\omega^2 r}{\beta \left( 1 + \alpha^2 \omega^2 r + \omega^4 \xi \right)} \right]^{1/5}. \quad (5.1)$$

For our sample system, the asymptotic approximation (5.1) gives $\sigma_1 \sim 23.0598 + 0.0952i$, which indeed is very close to the value of $\sigma_1$ shown in table 1. Expression (5.1) reveals that the 1st-mode short-crested flexural wave is the effect of the hydro-electromechanical coupling, sustained by the density difference at the water-plate interface. Note also that the smaller the stiffness of the plate $\beta$, the greater $\sigma_1$ and the shorter the wavelength $\lambda'_1$ of the 1st-mode flexural wave.

Let us now investigate the effect of the incident period on the generated power. Figure 6 shows the behaviour of the average extracted power (4.7) with respect to the period of the incident waves, for the sample piezoelectric plate studied in this section. The plot of figure 6 reveals the existence of resonant periods at which the extracted power is significant, with a maximum peak of about 4.4 kW at $T' \approx 5.4\,\text{s}$. Note that this value is about two orders of magnitude greater than the power output of piezoelectric beams predicted by simplified uncoupled models [9–11]. Clearly, the presence of sharp resonant peaks in the generated power is due to the coupled hydro-electromechanical behaviour of the device. This is studied in detail in the following subsection.
Figure 6. Wave power generated by a bimorph piezoelectric plate WEC of length $2L' = 20\,\text{m}$ and submergence $d' = 2\,\text{m}$ in water depth $h' = 10\,\text{m}$, versus the period of the incident wave. The parameters are: $A' = 1\,\text{m}$, $\alpha = 0.21$, $\beta = 3.8 \times 10^{-4}$ and the resistive term is $\xi = 1$. The first 13 modes have been considered.

(i) Resonance

Let us now analyse the resonant periods of figure 6, at which the power capture curve shows local peaks. Note that the average extracted power depends on the square of the plate curvature, see (4.8). Hence the short-crested component ($n = 1$) of the flexural waves (3.34) makes a leading contribution to the overall power capture of the system. As a consequence, we expect that the plate resonates when the wavelength of the 1st-mode flexural waves is close to one of the wavelengths of natural vibration of the plate. Physically, the natural vibrations are the solutions of the problem in which the plate performs free oscillations without damping. In our system, damping is associated with the PTO system and with the reflected and transmitted waves in regions 1 and 4, respectively. Therefore, to study undamped oscillations we must analyse the system in short-circuit condition ($\xi = 0$) and without surrounding water ($r = 0$). The governing equation for the flexural waves on the plate (3.23) becomes then

$$\beta w_{xxxx} - \omega^2 w = 0, \quad |x| < 1, z = -d \pm \delta, \quad \delta \to 0,$$

where $w(x) = (i/\omega) \phi_2|z = -d$ is the spatial displacement of the plate (see 2.19 and 3.19). In addition, the clamping conditions (3.24) give $w = w_x = 0$ at $x = \pm 1$. This yields a Sturm-Liouville problem whose general solution

$$w = A \cos(\mu x) + B \sin(\mu x) + C \cosh(\mu x) + D \sinh(\mu x)$$

admits the eigenvalues

$$\mu = \mu_p \simeq \left( p + \frac{1}{2} \right) \frac{\pi}{4}, \quad p = 1, 2, \ldots,$$

see [17]. Equating the latter expression to the approximated analytical form of the 1st-mode flexural wavenumber (5.1) in short-circuit conditions ($\xi = 0$), we obtain an approximated expression for the resonant periods of the system,

$$T'_p \simeq 16 \sqrt{\frac{rL'}{(p + 1/2)^2 \pi^4 g \beta}}, \quad p = 1, 2, \ldots$$

where (3.5) has been used to express the result in physical variables. In reality, we expect the resonant periods to be slightly greater than (5.4), because of the presence of dissipations...
Table 2. Resonant periods of the system in the interval \((4, 9)\) s and approximated values obtained with (5.4).

Figure 7. Damping coefficient (5.5) versus period of the incident wave. The parameters are the same as those of figure 6.

due to both radiation damping and wave energy extraction in the full problem, see [21]. The resonant periods predicted by the approximated formula (5.4) are reported in table 2 together with the actual values. The good agreement between the two sets of data confirms that the short-crested component of the flexural waves travelling on the plate is responsible for the resonant behaviour of the converter. Note that the resonant periods (5.4) are directly proportional to the density ratio \(\tau\) and the length of the device \(L'\), and inversely proportional to the stiffness of the system \(\beta\). Therefore, such parameters could be optimised to make the device resonate with the most energetic sea states in a given ocean sector. We are currently investigating random-sea optimisation techniques.

(b) Wave damping

We have anticipated in Section 1 that the piezoelectric plate WEC can also be an effective damper. In this section, we investigate the wave damping capacity of the device in more detail. Following Behera and Sahoo [27], define the dissipation coefficient as

\[
K_d = 1 - |R|^2 - |T|^2, \tag{5.5}
\]

where \(R\) and \(T\) are given, respectively, by (4.2) and (4.3). Figure (7) shows the behaviour of the dissipation coefficient \(K_d\) versus the period of the incident wave, in physical variables. Normally, the plate is able to reduce the amplitude of the surrounding waves only by a small proportion. However, if the plate is designed to resonate, energy dissipation increases and the damping effect of the plate can become significant. For the sample plate studied in this paper, the maximum damping coefficient is 20% at the resonant period \(T' = 5.4\) s, see again figure (7). This makes the
piezoelectric plate WEC a versatile device, which can provide a useful damping action around offshore oil platforms or in combination with nearshore breakwaters.

6. Conclusion

We have derived a fully coupled model of a piezoelectric plate wave energy converter. The semi-analytical solution of the problem was obtained by coupling a distributed-parameter model of the piezoelectric system with a potential-flow model of the water waves.

A novel hydro-electromechanical dispersion relation was obtained and solved in the complex wavenumber plane. The solution showed the existence of a coupled system of short- and long-crested weakly damped flexural waves in the plate region. As a consequence of this dynamics, the plate is forced to vibrate in short-crested oscillations slowly modulated by the long-crested wave. We showed that the short-crested component is responsible for the occurrence of resonant peaks in the power production of the device. At resonance, the system can extract a significant amount of energy, which can be used for low-power applications such as supplying LEDs, wireless routers, computers, sensors, etc. Finally, we showed that the piezoelectric device can act as a good wave energy damper when it resonates with the incident waves.

We made several simplifying assumptions to develop the mathematical model. First, we neglected the influence of the supporting structure of the plate on the wave field. In reality, a number of vertical struts would need to be used to support the clamps. These might have an effect on the wave field, which could be analysed with computational fluid dynamics (CFD) software. Second, we neglected the presence of voltage cancellations in the short-wave vibration mode of the plate. We remark that the present model is valid only if the length scale of the plate deformation is greater than the length of each patch, i.e. $\lambda_1 > dX$. If this assumption is violated, voltage cancellations may occur, see Jbaily and Yeung [4]. In that case, one must use segmented electrodes to avoid cancellation, which would then require the definition of separate voltage terms, as described by [8]. Third, in the case of obliquely incident waves, three-dimensional effects could become relevant and would need to be modelled appropriately. We are currently developing a full numerical model based on a finite-element approximation of the boundary-value problem. This can be easily extended to handle arbitrary geometrical shapes of the plate in three dimensions. However, we emphasise that the semi-analytical model developed in this paper offers a valuable physical insight into the problem, which the numerical model cannot provide.

Mathematically, we solved the coupled hydro-electromechanical boundary-value problem using separation of variables and the method of matching potentials, as in [24,27]. Hassan and Meylan [24] already pointed out that the eigenfunction-matching method does not have optimal convergence rates because of the singularity at the plate tip. However, more analytic approaches such as the Wiener-Hopf technique or the residue calculus method require structures of semi-infinite length along the $x$-axis [24], and so could not be applied to this study. Note also that the analysis was performed in the framework of a linearised theory for both the plate deformation and the wave motion. Close to resonance, the displacements of the plate might become significant and a nonlinear analysis should be carried out to refine the power output predictions.

Our current research efforts are oriented towards determining the parametric behaviour of the system in order to find optimal device configurations. Due to the large number of parameters (e.g. $\alpha, \beta, \xi, \omega, d, h, r$, etc.) and the large extent of the parametric space, we are using genetic algorithms to map the parametric behaviour of the system and identify areas of high-quality solutions in the space of parameters. This will allow us to obtain a database of possible PWEC configurations of interest to the wave energy industry.

Appendix A

In this Section, we provide some details on the numerical solution of the coupled hydro-electromechanical model of Section 3. The model is based on the solution of the linear system of equations (3.41),(3.43)–(3.48). This is achieved numerically by truncating the series expansions up to a suitable number of terms, $N$. To determine an appropriate value for $N$ in our numerical calculations, we performed a convergence test by analysing the influence of $N$ on the reflection and transmission coefficients of the system, respectively (4.2) and (4.3). To assess convergence, we used the combined tolerance test [30], in which the error at the $n$th numerical iteration is calculated as

$$
\epsilon_n = \frac{|x_{n+1} - x_n|}{\max \{1, |x_{n+1}|, |x_n|\}}. \quad (6.1)
$$

In the latter, $x_n$ is the value of the assessed quantity (either $R$ or $T$) at the $n$th numerical iteration. Already with $N = 8$ the error $\epsilon_N$ is of the order $O(10^{-2})$ and decreases to $O(10^{-3})$ with $N = 9$. The latter is accurate enough for graphical purposes in all cases considered here. Figure 8 shows the behaviour of the absolute values of the transmission and reflection coefficients versus the nondimensional parameter $k_0h$, for three different values of $N$. Note that there is practically no visible difference between the cases $N = 9$ and $N = 10$, so that $N = 9$ provides an adequate level of convergence. That corresponds to considering up to 12 flexural modes on the plate, $n = -2, -1, ..., 9$.
