Control of Second Life Hybrid Battery Energy Storage System based on Modular Boost-Multilevel Buck Converter

Abstract—To fully utilize second life batteries on the grid system a hybrid battery scheme needs to be considered for several reasons; the uncertainty over using a single source supply chain for second life batteries, the differences in evolving battery chemistry and battery configuration by different suppliers to strive for greater power levels and the uncertainty of degradation within a second life battery. Therefore, these hybrid battery systems could have widely different module voltage, capacity, initial SOC and state-of-health (SOH). In order to suitably integrate and control these widely different batteries, a suitable multi-modular converter topology and associated control structure are required. This paper addresses these issues proposing a modular boost-multilevel buck converter based topology to integrate these hybrid second life batteries to a grid-tie inverter. Thereafter, a suitable module based distributed control architecture is introduced to independently utilise each converter module according to its characteristics. The proposed converter and control architecture are found to be flexible enough to integrate widely different batteries to an inverter dc-link. Modelling, analysis and experimental validation are performed on a single phase modular hybrid battery energy storage system prototype to understand the operation of the control strategy with different hybrid battery configurations.

Index Terms—Second life hybrid batteries, modular boost-multilevel buck converter, distributed control strategy, boost-buck control mode.

NOMENCLATURE

- \( V_{\text{bat},i} \): Battery terminal voltage of \( i \)th module (V)
- \( i_{\text{bat},i} \): Battery current of \( i \)th module (A)
- \( \alpha_i \): Desired weighting factor for \( i \)th module current
- \( i_{\text{dc},i} \): Instantaneous dc-link current of \( i \)th module (A)
- \( i_{\text{dc},i,\text{avg}} \): Steady state dc-link current of \( i \)th module (A)
- \( V_{\text{dc},i} \): DC-link capacitor voltage of \( i \)th module (V)
- \( V_{\text{dc},i,\text{avg}} \): Desired module dc-link capacitor voltage (V)
- \( V_{\text{dc},i,\text{ref}} \): Small signal value of \( i \)th module current (A)
- \( V_{\text{dc},i,\text{bias}} \): Small signal \( i \)th module dc-link voltage (V)
- \( V_{\text{dc,c}} \): Desired central DC-link capacitor voltage (V)
- \( I_{\text{dc}} \): Average DC-link current (A)
- \( i_{\text{dc}} \): Instantaneous value of DC-link current (A)
- \( V_{\text{sw}} \): Maximum switch voltage rating of module (V)
- \( d_i \): Instantaneous duty cycle of switches \( S_i, S_i^\prime \)
- \( d_{\text{avg}} \): Overall duty cycle of multilevel buck converter
- \( d_{\text{avg}} \): Instantaneous duty cycle of switches \( T_{ii}, T_{ii} \)
- \( D_i \): Average duty cycle of switches \( S_i, S_i^\prime \)
- \( D_{\text{avg}} \): Average duty cycle of switches \( T_{ii}, T_{ii} \)
- \( C \): Module dc-link capacitance (F)
- \( L \): Module boost inductance (H)
- \( L_{\text{dc}} \): DC-link inductor (H)
- \( R \): leakage resistance of the boost inductor/module (Ω)
- \( R_{\text{dc}} \): leakage resistance of the dc-link inductor (Ω)
- \( Q_{\text{max},i} \): Battery capacity of the \( i \)th module (Ah or C)
- \( OCV_{i,0} \): Initial open circuit voltage of \( i \)th battery module (V)

I. INTRODUCTION

Significant research has been carried out on battery energy storage systems (BESS) using a single type of battery with homogeneous characteristics where a single dc-dc or dc-ac converter interface with the battery bank is used both in grid-tie and in microgrid applications [1] – [4]. This paper is concerned with hybrid second life battery systems e.g. reusing EV/HEV batteries in grid support applications because there is a significant interest in using these transportation batteries to help support the new smart grid functionalities [5] – [7]. The main advantage of these batteries are the supposed lower cost and the chance to delay the development of the second life battery recycling chain which is in its infancy due to changing battery chemistry and the impact on the recycling process cost. These second life batteries are likely to trickle through the battery recyclers (at a module level) and therefore to get a sufficiently large system for grid support will require the use of different manufacturer’s batteries. Each battery in the system could have a different chemistry, voltage, capacity, initial State of Charge (SOC). As a battery fails it would be desirable to hot-swap it for one that works resulting in a hybrid mix encompassing everything from new batteries to batteries close to failure at any moment in time.

To meet the requirements for integrating together hybrid energy storage systems, multi-modular power converters (cascaded/parallel) are preferred [8] – [9]. Previous research on such hybrid energy systems with batteries has mainly focused on generation-storage hybridization for example; batteries with super-capacitor, batteries with PV/wind or fuel cells [10] – [12]. These researches use the same type of battery system and focus on power sharing between the battery and other sources to increase battery useful life or smoothing the mismatch between the generation and demand.

In some cases, multi-modular converters are also used for power sources of the same type but under different operating conditions. For example, they can be used for PV systems under partial shading [13] – [14] using multi-modular dc-dc converters with a single inverter to deal with the heterogeneous nature of PV panels under MPPT conditions. Several authors have compared and recommended cascaded dc-dc converters over a parallel structure due to increased efficiency and reduced size and/or cost [13]. In that research, boost type modules were preferred for low module voltages where the total dc-side voltage is less than the inverter dc-link voltage, whereas buck type modules were suggested for the case of higher module voltages (higher than the inverter dc-link). From a control point of view, a cascaded boost converter
neither can deliver the peak power from a module under all inhomogeneous radiation conditions, nor can it provide the fault tolerance without extra protection, whereas a cascaded buck structure is capable of handling both situations. In order to address the shortfall of a cascaded boost structure, a separate string diverter was proposed in [15] which could solve power mismatch problems but not the problem of integrating widely uneven module voltages together. Therefore, these three problems: a) integrating widely different voltage modules to an inverter dc-link b) fault-tolerance and hot-swapping and c) distributed utilisation of different modules have been looked at in different contexts but not together in a hybrid energy system.

These are important and relevant issues in second life battery integration as the vehicle batteries, for example, come in the range of 12/24V up to 600V with ratings of 0.5kWh up to 50kWh. The smallest accessible module may be anything from a cell to a complete system. As a result, depending on the battery availability, the overall battery side voltage can be greater or less than the desired dc-link voltage of the line side inverter under normal operation which makes it difficult to integrate them to a common inverter dc-link using either a boost or a buck type modular converter. Moreover, in order to control these hybrid batteries according to their characteristics each module may need to be charged or discharged at significantly different current levels within the converter. As a result, the integration of such hybrid batteries is challenging both in terms of converter topology and control.

There are no research reports to date about the power converter interface and control issues to integrate widely different battery types (new/second life) into a single grid-tie converter. To overcome these shortfalls, this paper proposes a modular boost-multilevel buck dc-dc converter topology based on a cascaded structure to integrate hybrid second life battery modules to a common inverter dc-link irrespective of their voltage levels and characteristics. Moreover, a generalised distributed control structure has been introduced for the proposed converter which allows control of each converter module independently through a weighting function to optimally utilize different battery modules depending on their relative characteristics within a set of hybrid batteries. The paper is structured as follows: converter topology is presented in section II, dynamic modeling, power sharing and distributed control structure are given in section III, section IV and section V respectively. The experimental validation is provided in section VI and section VII concludes the paper.

II. CONVERTER TOPOLOGY

This paper describes an H-bridge cascaded boost-multilevel dc-dc converter based topology with an inverter as shown in Fig. 1. This topology offers a good compromise between the cost, efficiency and reliability while maintaining the flexibility to deal with different battery voltages and power levels. By choosing an H-Bridge module, the converter can be operated in any of boost, buck and boost-buck mode by independently controlling the two legs of an H-bridge to enable different battery voltages to be dealt with for a required dc bus voltage with a narrow voltage range for grid inversion.

A boost type module is generally considered when all the dc-sources, be they, generation or batteries have low voltages which meets the condition $\sum V_{\text{batt},i} < V_{dc}$. However, this structure is not fault-tolerant and has an inherent current limitation ($i_{\text{batt},i} \geq I_{dc}$) which makes them unsuitable when module currents demand to be lower the dc-link current.

On the other hand, a Buck type module could be used only when all the dc-sources meet the condition $\sum V_{\text{batt},i} > V_{dc}$. The main advantages of a buck type module are: a) the ability to utilise a module better than a boost module because it is possible to make $i_{\text{batt},i} \leq I_{dc}$, b) fault-tolerant in nature (does have module bypassing capability). However, there are some limitations of this mode also which includes the need for a large number of modules if only low voltage batteries are available and the input current is discontinuous which adds the requirement for a high input capacitor across each battery module which increases the overall system size and cost.

A buck-boost module configuration has previously been compared to a boost and buck configuration for systems with mixed voltages [13]. The author concluded that there was poor switch utilization, low converter efficiency, large capacitors on both inputs and outputs which possibly increase the module size/cost and reduces the reliability of a converter module. Moreover, the requirement of different switch rating/module makes the module selection and design difficult.

In order to overcome the above drawbacks, a modular boost-multilevel buck configuration is used with a single multi-switch buck converter. The proposed configuration uses a boost module with each battery bank and then adds a half-bridge in parallel with each module capacitor to make it fault-tolerant in boost mode and provide an opportunity to switch in the buck mode (if needed). Thereafter, these half-bridges are connected in cascade through a single inductor to integrate all the modules to a common dc-link voltage as shown in Fig 1(a). Due to having a boost module at the input of each module, it can avoid an input capacitor due to the continuous current and the overall design of a module becomes easier because of the uniform voltage rating for all the devices.

A. Principle of Operation

Each input converter ($S_i, T_i$) can work in PWM mode to form the module capacitor voltages $V_{dc,1}, V_{dc,2} \ldots V_{dc,n}$ and then the cascaded half-bridge switches ($T_i, T_c$) can be operated as a multilevel buck converter [16] to maintain the desired central dc-link voltage ($V_{dc}$). In this way, the converter behaves as a two-stage dc-dc converter as indicated in Fig 1(a). The topology configuration offers a large degree of flexibility, using an appropriate combination of module switches ($S_i, T_i$) where each module may be operated in boost (buck module bypassed, $T_i, T_c$ in idle), in buck mode (with the boost module bypassed, $S_i$ in idle) or in boost-buck mode ($S_i, T_i$ and $T_c, T_c$ in PWM) as shown in Table I. The application range, expressed as $\sum V_{\text{batt},i}$ against the control flexibility (as a range of $i_{\text{batt},i}$) has been shown in Fig 1(b) to understand the operational envelope of the proposed converter in different modes. It can be seen from Fig 1(b) that the boost and the buck mode offer a narrow operating envelope on the plane.
The boost mode suffers from a current limitation problem while a buck mode has an inherent voltage limitation issue. The boost-buck mode provides a wide control flexibility (\( i_{\text{batt},i} \geq l_{dc} \) and \( i_{\text{batt},i} \leq l_{dc} \)) over any application range (\( \sum V_{\text{batt},i} > V_{dc} \) and \( \sum V_{\text{batt},i} \leq V_{dc} \)) within a pre-defined design envelope. Therefore, this mode is more suitable to integrate widely different characteristics batteries to an inverter dc-link. Within each module the battery cells have balancing circuits similar to [17] – [18] in order to uniformly utilise each cell in a module.

### B. Module Design

The design of an H-bridge module, inductor and capacitor is challenging because of the uneven module voltages and potential variation of module current. There are two approaches: a) designing different module switch ratings and inductor/capacitor values according to individual module battery parameters or b) designing a uniform switch rating and inductor/capacitor by pre-defining a maximum battery voltage and current envelope. The latter approach has been followed in this work because different switch rating and passive component ratings in different modules complicates the design of the modular converter and prevents hot-swapping of a battery module. A battery size envelope was used to choose the appropriate switch rating. The boost inductor was chosen to give a maximum of 5% current ripple as calculated in (1) where \( D_{\text{max}} \) is the maximum duty cycle, \( V_{\text{batt},i} \) is the magnitude of the ripple current, \( T_i \) is the switching time and \( V_{sw} \) is the maximum switch voltage rating. \( V_{sw} \) is chosen to be 5 the times maximum battery voltage (to account for a reasonable boost ratio and a margin of around 20%).

\[
L = \left( 1 - \frac{\text{max}(V_{\text{batt},i})}{V_{\text{sw}}} \right) \times \frac{\text{max}(V_{\text{batt},i})}{0.05 \times \text{max}(V_{\text{batt},i})} T_i \tag{1}
\]

Similarly, the design of the module capacitor was set to correspond to a maximum allowable voltage ripple, \( \Delta V \), on the module (set to 1% of the dc-bus voltage) as shown in (2).

\[
C = \left( 1 - \frac{\text{max}(V_{\text{batt},i})}{V_{\text{sw}}} \right) l_{dc} T_i, \text{ } \Delta V = 0.01 \times \text{max}(V_{dc,i}) \tag{2}
\]

## III. CONVERTER MODELLING

The dynamic modelling of the converter in Fig 1(a) is composed of two-stages: a) modelling input boost converter, b) modelling of modular multilevel buck converter.

### A. Input side boost converter

The dynamic equations for the input side boost converter can be written as follows considering \( n \) converter modules:

\[
\frac{d l_{\text{batt},i}}{dt} + Ri_{\text{batt},i} + (1 - d_i)V_{dc,i} = V_{\text{batt},i} \forall \ i = 1 \ldots n \tag{3}
\]

\[
C \frac{dV_{dc,i}}{dt} - (1 - d_i)i_{\text{batt},i} = -i_{dc,i} \forall \ i = 1 \ldots n \tag{4}
\]

\[
\langle V_{dc,i} \rangle_{av} = \frac{1}{1 - d_i} V_{\text{batt},i} \forall \ i = 1 \ldots n \tag{5}
\]
It is necessary to investigate the model to accurately predict the dynamics of the control system. The required small model can be expressed by the state-space equations as shown in (6) employing two state-variables \( V_{dc,i} \) and \( i_{batt,i} \) per module.

\[
\dot{X} = \left( \frac{-R}{L} \frac{1}{(1-D_l)} \right) X + \left( \frac{1}{L} \frac{v_{dc,i}}{L} \frac{0}{\frac{1}{C}} \right) U \forall i = 1 \ldots n
\]

Where, \( X = \left( \frac{i_{batt,i}}{V_{dc,i}} \right) \), \( U = \left( \frac{v_{batt,i}}{d_{av}} \right) \)

\( d_{av} = \frac{v_{dc}}{\sum v_{dc,i}} \sum V_{dc,i} \forall i = 1 \ldots n \)

\( l_{bc,i} = D_l \forall i = 1 \ldots n \)

\( c_{dc} \frac{d v_{dc,i}}{d t} = l_{dc} - i_{inv} \)

The state-space model of multilevel buck converter can be written as following:

\[
\dot{X} = \left( \begin{array}{ccc}
\frac{-R}{L} & \frac{1}{L} & 0 \\
\frac{1}{C_{dc}} & 0 & 0 \\
1 & 0 & 0
\end{array} \right) X + \left( \begin{array}{c}
\frac{d_{av}}{L} \\
\frac{v_{dc,i}}{L} \\
0
\end{array} \right) U \forall i = 1 \ldots n
\]

Where \( X = \left( \frac{V_{dc,i}}{d_{av}} \right) \), \( U = \left( \frac{v_{dc,i}}{d_{av}} \right) \)

\( V_{dc,i} l_{dc,i} = \eta_i v_{dc,i} i_{batt,i} \forall i = 1 \ldots n \)

\( D_l l_{dc} = V_{dc,i} i_{batt,i} = (1-D_l) i_{batt,i} \forall i = 1 \ldots n \)

\( i_{batt,i} = \frac{D_l}{(1-D_l)} l_{dc} \forall i = 1 \ldots n \)

It can be seen from (14) that a module current can be controlled to more or less than the dc-link current \( l_{dc} \) using an appropriate combination of \( D_l \) and \( D_i \). If \( i_{batt,i} > l_{dc} \) then the condition \( (D_l + D_i) > 1 \) needs to be satisfied. For \( i_{batt,i} < l_{dc} \) the condition \( (D_l + D_i) < 1 \) needs to be fulfilled.

### IV. Power Sharing Strategy

The control/power sharing of modular energy storage systems has been done previously using a single type of batteries or super-capacitor concentrating on the balancing control e.g. voltage/SOC among the modules [19 – 20]. A distributed power sharing was performed in mainly PV system where the modular dc-dc converters were controlled according to the distributed MPPT [21 – 22]. However, the major differences between PV systems and a hybrid battery system are: a) control architecture in PV system is mainly unidirectional whereas in BESS it has to be bidirectional, b) the criteria for distributing the power between modules is dependent on multiple battery parameters such as, voltage, capacity etc. unlike in PV system which is solely dependent on different radiation conditions.

The distributed sharing proposed in the paper is based on weighting factors \( (\omega_i) \) which represent the status (“goodness” or “badness”) of each battery module on an instantaneous basis as presented in (15). Since each of these hybrid module types will charge/discharge at different rates and have different maximum/minimum safe amounts of charge and voltages, the weighting factor based strategy ensures that the charging/discharging trajectory of the hybrid modules during a charging or discharging cycle will all arrive at their maximum or minimum values at the same time. The detailed derivation of the weighting factor is presented in the Appendix.

\[ \frac{i_{batt,1}}{\omega_1} = \frac{i_{batt,2}}{\omega_2} = \ldots = \frac{i_{batt,n}}{\omega_n} \times f(V_{batt,i}, OCV_{0,i}, Q_{max,i}) \]

\[ (15) \]

### V. Distributed Control Architecture

Since the relative weighting factors (i.e. \( \omega_i \)) can be significantly different in this hybrid battery integration, the proposed control structure employs the boost-buck control mode to achieve a wide operational envelope as shown in Fig 1(b). The main objectives of the control architecture are: a) to control the central dc-bus \( V_{dc} \) to a fixed value irrespective of set of batteries present to allow the line side inverter to respond according to the desired grid side power demand, b) to control the hybrid battery modules according to the desired battery weighting factors to optimally utilise them.

The principle concept of the proposed distributed control is to control the input side boost converters \( (S_a, S_b) \) to form equal module dc-link voltages irrespective of their input voltages and then utilise a concept of distributed duty ratio \( (d_i \forall i = 1 \ldots n) \) of the buck converter switches \( (T_i, T_j) \) as a function of battery weighting factors \( (\omega_i) \). This control operation makes the converter behave as a multilevel converter as indicated by the effect of the different module duty ratio’s in Fig 1(c). There could be two possible cases depending on the set of batteries present: a) a similar set of batteries present, b) a widely different batteries present. Two different control techniques have been described.
A. Case 1 – All modules in boost-buck mode (dc-side control)

This control is used where all the modules are operated in boost-buck mode, e.g., all modules have similar voltages 12V with 24V etc. The module input voltages are boosted to $V_{dc,i}$, $V_{dc,2}$ ... $V_{dc,n}$ using the input side boost converters ($S_i$, $S_{ii}$ \(\forall i = 1 ... n\)) and then the overall voltage ($\sum V_{dc,i}$) is bucked using the multilevel buck converter ($T_i$, $T_{ii}$) to maintain the central inverter dc-link voltage constant at the time. All the module boost converters are controlled to a same voltage reference $V_{dc,m}^*$ independent of the weighting factors where the upper limit is limited by the maximum switch rating $V_{sw}$ of a module as shown in (16). The desired module independent control is achieved using the duty ratios $d_i \forall i = 1 ... n$. The derivation is presented in (17) – (19) using (12) assuming $\eta = 1$.

\[
nV_{dc,m}^* > V_{dc}^* \rightarrow V_{dc,n}^* < V_{dc,m}^* \leq V_{sw} \quad (16)
\]

From (12), $V_{dc,i}i_{dc,i} = V_{dcm}(d_{ii})I_{dc} \approx V_{batt,i}i_{batt,i}$ therefore,

\[
d_{ii} \propto V_{batt,i}i_{batt,i} \forall i = 1 ... n \quad (17)
\]

From (15), if $i_{batt,i} \propto \omega_i \forall i = 1 ... n$ then from (17)

\[
d_{ii} \propto \omega_i V_{batt,i} \forall i = 1 ... n \quad (18)
\]

According to (8),

\[
d_{av} = \frac{\Sigma V_{dc,i}d_{ii}}{\Sigma V_{dc,i}}
\]

After putting $V_{dc,i} = V_{dc,m}$ \(\forall i = 1 ... n\) in (8)

\[
d_{av} = \frac{V_{dcm}(\Sigma d_{ii})}{nV_{dc,m}} \rightarrow \Sigma d_{ii} = nd_{av}
\]

Therefore, $d_{ii} = nd_{av} \frac{\omega V_{batt,i}}{\Sigma \omega_i V_{batt,i}} \forall i = 1 ... n \quad (19)$

B. Case 2 – Boost-k out of n modules only in buck mode (dc-side control)

This dc-side control is different, where not all the modules can operate in boost-buck mode. For example, where the battery module voltages are considered to be substantially different e.g. 24V with 220V etc. or when the switch rating is not sufficiently high enough to allow the boost operation of a higher voltage connected battery. A control strategy to deal with this is: a) to operate the higher input voltage module only in buck mode with the corresponding boost converters ($k$) in idle mode which means $S_k, S_{ii}$ in idle ($V_{dc,k} = V_{batt,k}$) and $T_k, T_{ii}$ in PWM, b) to operate the remaining modules ($n-k$) in boost-buck mode as previously described which means $S_i, S_{ii}$ in PWM and $T_i, T_{ii}$ in PWM \(\forall i \neq k\). The module voltage reference ($V_{dc,m}^*$) is calculated in (20) and the duty ratio distribution is derived in (21) to (24).

\[
(V_{dc}^*-\Sigma \omega_i V_{batt,k}) < V_{dc,m}^* < V_{sw} \forall i \neq k \quad (20)
\]

From (12), $V_{dc,i} = V_{dcm}$, $d_{ii} \propto \omega_i V_{batt,i} \forall i \neq k = 1 ... n$

For the ($k$) modules in buck mode, from (12),

\[
V_{dc,k} = V_{batt,k} \quad \forall i \neq k \quad (21)
\]

Now with the help of (8), following expressions are derived:

\[
V_{dcm} \Sigma_{i \neq k} d_{ii} + \Sigma_{k} V_{batt,k}d_{kk} = d_{av} (n-k)V_{dc,m} + \Sigma_{k} V_{batt,k} \quad (22)
\]

Equating, $V_{dc,m} \Sigma_{i \neq k} d_{ii} = d_{av} (n-k)V_{dc,m}$ and

\[
\Sigma_{k} V_{batt,k}d_{kk} = d_{av} \Sigma_{k} V_{batt,k} \quad (23)
\]

\[
\Sigma_{i \neq k} d_{ii} = (n-k)d_{av} \quad (23)
\]

\[
d_{av} = \frac{\Sigma_{k} V_{batt,k}d_{kk}}{\Sigma_{k} V_{batt,k}}
\]

---

Fig 2 Proposed dc-side distributed control architecture of the converter: a) module boost converter control, b) multilevel buck converter control
Now using (18) and (21) the following expressions can be derived
\[ d_{ii(k)} = (n - k) d_{av} \frac{\omega_t V_{batt,i}}{\sum k \omega_t V_{batt,k}} \]
and
\[ d_{kk} = d_{av} \frac{\omega_t \sum k V_{batt,k}}{\sum k \omega_t V_{batt,k}} \]

Where \( d_{ii} = d_{av} \) for \( k = 1 \) (24)

C. Overall Control Structure

The detailed control structures for both the dc-side and the ac-side are shown in Fig 2 and Fig 3 respectively. The dc-side control (Fig 2) is composed of two-stages: a) control of the boost converter and b) control of the multilevel buck converter. The module boost converters are controlled by the same voltage reference \( (V_{dc,n}) \) using an outer PI-voltage loop and an P-inner current loop. The selection of this reference is done using (16) or (20). The proposed control structure of the multilevel buck converter is shown in Fig 2(b). It consists of two-stages: i) battery parameter estimation and weighting factor generation and ii) closed loop control. The control employs a central dc-bus voltage loop and the output of that controller provides the overall duty ratio \( d_{av} \) command through an inner dc-link current controller. Thereafter, this \( d_{av} \) is split into module duty ratios \( d_{av} \) using (19) or (24) which maintains \( V_{dc} \) as well as control the module currents in the desired manner. The grid side control (Fig 3) depends on the type of application of the energy storage system e.g. voltage control or the frequency control. The output of the voltage or frequency controller provides the reference for the inner q-axis (active power axis) current loop. The d-axis is taken as the reactive power axis. This \( i_{dq} \) plays an important role because the weighting factor for charging and discharging is different on the dc-side. The sign of \( i_{dq} \) indicates the phase of line side current with respect the line voltage. Therefore, this dynamic change-over is performed using the sign of \( i_{dq} \) though an edge detector as shown in Fig 2(b). The initial OCV is updated at the end of charging and discharging cycle. This is performed through a sample and hold (S/H) logic and an edge detector using the \( i_{dq} \) as shown in Fig 2(b).

VI. EXPERIMENTAL INVESTIGATION

A four-module or five-level hybrid battery energy storage system has been built as shown in Fig 4 and tested in a grid connected condition to validate the proposed control. Different converter modules contain different batteries in terms of chemistry/type, voltage, capacity. Initial characterizations such as pulse load tests [25] have been performed to find the parameters of a module before putting it into a converter module as shown in Table II. The inverter was controlled to meet a fixed grid side power demand.

A. Multilevel Operation

In order to show the multilevel operation of the converter, the voltage \( V_{AB} \) in Fig 1(a) is measured. Since all the switches \( T_i \), \( T_{ii} \) operate in different duty ratio depending on weighting factors, this voltage varies between zero and a combination of the different voltage levels e.g. \( V_{dc,m} \), 2\( V_{dc,m} \), 3\( V_{dc,m} \), 4\( V_{dc,m} \) at switching frequency. Fig 5a shows this operation. It can be seen that there is five distinct voltage levels of the converter.
B. Distributed Power Sharing (Current Dynamics)

Mode – 1 zero to discharging mode: Fig 5b shows the experimental result for the distributed control scheme at the moment of connecting to the grid. It can be seen that the converter distinctly utilises the hybrid modules where the module currents are almost in 1:8 ratio. The module currents are dependent on the weighting factors. Table III shows the comparison of calculated and measured currents

Mode – 2 zero to charging mode (current dynamics): Fig 5c shows the experimental result when the converter switches to charging mode. The second module is charged at a significantly higher current than the remaining modules. Module currents are widely different (1:10 ratio exists between the highest and lowest module currents). The steady state values of module currents are presented in Table III.

Mode – 3 charging to discharging mode (current dynamics): Fig 6(a) shows the experimental result when the converter switches from charging mode to discharging mode. It is important to note that the current sharing between the modules is different in charging and in discharging due to the differences in weighting functions between the two modes. The details are given in Table III.

Mode – 4 discharging to charging mode (current dynamics): Fig 6(b) shows the experimental result when the converter switches from discharging mode to charging mode. It is to be noted that the all the module currents in charging and discharging mode are different and the current sharing changes after switching from discharging to charging mode.

C. Module Bypassing (Current Dynamics)

Fig 6(c) shows the experimental result of module bypassing during discharging. In this experiment, module – 4 has been bypassed. The remaining modules clearly take a higher share of the currents to keep the power. A momentary drop in the currents occurs due to the sudden dip in \( V_{dc} \) but then recovers quickly. This shows the fault tolerance of the converter.
D. Duty ratio Distribution

The converter in Fig 1 operates in boost-buck fashion where the \( S_i, S_o \) operates in PWM mode to form the module dc-link voltages and \( T_i, T_o \) operates in PWM fashion to utilize the hybrid modules. Fig 7 shows how the duty ratios are used to change the power sharing during the transition of modes. Fig 7(a) shows the distribution of module duty ratio while switching from charging to discharging and Fig 7(b) shows the similar waveform while moving from discharging to charging mode. On the other hand, Fig 7(c) shows the module duty ratio distribution when module \( -4 \) bypasses. It can be seen that the module duty ratios \( (d_i) \) re-distributes among themselves to keep the overall duty ratio \( (d_{av}) \) constant all the time because the total dc-bus voltage \( (V_{dc}) \) is controlled to a desired value through a central voltage loop as shown in Fig 2.

E. Module voltage dynamics

Fig 8 shows the dynamics of module dc-link voltages \( (V_{dc,i}) \) at the start up. Note that all the voltages are equal in steady-state as expected from the design presented in section V after undergoing slightly different transient response.

F. Validation of overall control

Fig 9 shows the experimental results for grid side and dc-link side control system operation at a moment in time when the inverter is switched from the charging to discharging mode. It can be seen that the phase angle of the line side current changes with respect to the line voltage when the dc-link current \( (I_{dc}) \) moves from negative to positive. It is to be noted that the total DC-link voltage \( (V_{dc}) \) stays constant during the transition.

G. Converter Efficiency

The overall converter efficiency was measured in two steps: a) efficiency of the modular dc-dc converter consisting of four modules, b) efficiency of the overall grid-tie converter along with the inverter efficiency. The cascaded boost-multilevel buck converter from the experimental setup has a measured efficiency of around 96% at a 10 kHz switching frequency. The cascaded converter has a high efficiency because the LV Trench MOSFETs used in the H-Bridge module have a very low on-state resistance \( (R_{on} = 8m\Omega) \). The overall efficiency of the converter was found to be around 92% when the inverter is included in the calculation, however there is scope to improve this using more efficient devices in the inverter.
is reduced while that taken by the remaining modules is increased and the discharging trajectory continues as expected. In this way, the proposed strategy remains valid.

VII. CONCLUSION AND FUTURE WORK

A modular boost- multilevel buck based converter topology and a module based distributed control architecture based on weighting function are proposed, analysed and experimentally validated to integrate any set of second life batteries to a grid-tie energy storage system and to optimally utilise them. The proposed converter is found to be efficient and is capable of utilising widely different battery modules characteristics using boost-buck control mode. The control structure is based on weighting factors which are dependent on module battery characteristics such as, initial SOC, voltage impedance and capacity in order to take account their different performances. The results show the suitability of the topology and control structure when widely different batteries are present. The application is focused on single-phase but the proposed converter structure and control architecture can be extended into three-phases and also other multi-modular energy systems.

APPENDIX – WEIGHTING FACTOR DERIVATION

The strategy adopted in this paper is to ensure that the charging/discharging trajectory of the hybrid battery modules during a charging or discharging cycle will all arrive at their maximum or minimum values at the same time. The following assumptions have been taken:

- A battery capacity has been taken as the maximum charge left ($Q_{max}$ in C or Ah) that a battery can deliver to a load.
- A battery is modelled as an open circuit voltage (OCV) with series impedance ($Z$) → $V_{batt,i} = OCV_i \pm i_{batt,i}Z_i$.
- Each battery module have different initial SOC (or $OCV_{0,i}$) at start, different nominal voltages and also different capacity ($Q_{max,i}$).

A. Weighting Factor

The fundamental charge equation for a module is given by (A.1) where the $Q_0$ is the initial charged stored. Now assume, the module battery charge $Q(t)$ is some function $f(.)$ of its open-circuit voltage $OCV(t)$:

$$Q(t) = Q_0 + \int_0^T i_{batt} dt = f(OCV(t))$$

(A.1)

Therefore,

$$f(OCV(t)) = f(OCV_0(t)) + \int_0^T i_{batt} dt$$

(A.2)

Where, $OCV_0$ is the measured module open-circuit voltage at time $t=0$ (V). This $OCV_0$ indicates the initial SOC. For the charging/discharging strategy chosen at some time $T=T_{minmax}$ where the charging/discharging process must cease.

Therefore, $OCV(t)_{@T_{minmax}} = OCV_{minmax}$

(A.3)

$OCV_{minmax}$: module maximum or minimum open-circuit voltage at time $T_{minmax}$. Under these conditions (A.2) becomes:

$$f(OCV_{minmax}) = f(OCV_0) + \int_0^{T_{minmax}} i_{batt} dt$$

(A.4)

Re-arranging in terms of the module charging current gives:
\[ \int_0^{T_{\text{minmax}}} i_{\text{batt}} \, dt = f(\text{OCV}_{\text{minmax}}) - f(\text{OCV}_0) \quad (A.5) \]

Equation (A.5) can be solved for an approximately constant charging/discharging current conditions as follows:

\[ I_{\text{batt}} = \frac{f(\text{OCV}_{\text{minmax}}) - f(\text{OCV}_0)}{T_{\text{minmax}}} \quad (A.6) \]

Where \( I_{\text{batt}} \) is the signed magnitude of the constant charging/discharging current (A).

In equation (A.6), \( \text{OCV}_{\text{minmax}} \) should be known for a particular module based on pre-characterization and \( \text{OCV}_0 \) can be measured taking the first sample instant of open circuit voltage (OCV) calculated from the battery model (= \( V_{\text{bat}} \pm I_{\text{batt}} Z \)) as a charge/discharge cycle begins.

However, in a typical grid support application, \( T_{\text{minmax}} \) will be unknown to the hybrid modules. To eliminate \( T_{\text{minmax}} \) from (A.6), the converter power balance equation can be used as shown below.

\[ P = \sum_{k=1}^{n} V_{\text{batt},k} I_{\text{batt},k} \quad (A.7) \]

Where \( n \) is the number of active modules and each module \( k \) has a different voltage, \( V_{\text{batt},k} \) and current \( I_{\text{batt},k} \).

Now, substituting (A.6) into (A.7) for each module \( k \), gives:

\[ P = \sum_{k=1}^{n} V_{\text{batt},k} \frac{f(\text{OCV}_{\text{minmax}},k) - f(\text{OCV}_{0,k})}{T_{\text{minmax}}} \quad (A.8) \]

To find, say, \( I_{\text{batt},t} \) and eliminate \( T_{\text{minmax}} \) from (A.8) which is equal for all modules, substitute for \( T_{\text{minmax}} \) from (A.6):

\[ P = \sum_{k=1}^{n} V_{\text{batt},k} \frac{f(\text{OCV}_{\text{minmax}},k) - f(\text{OCV}_{0,k})}{f(\text{OCV}_{0,k}) - f(\text{OCV}_{0,1})} \quad (A.9) \]

Re-arranging (A.9) gives the desired module battery current:

\[ I_{\text{batt},1} = \left( \sum_{k=1}^{n} V_{\text{batt},k} \frac{f(\text{OCV}_{\text{minmax}},k) - f(\text{OCV}_{0,k})}{f(\text{OCV}_{0,k})} \right) \text{ or } (A.10) \]

\[ I_{\text{batt},t} = \left( \sum_{k=1}^{n} V_{\text{batt},k} \frac{f(\text{OCV}_{\text{minmax}},k) - f(\text{OCV}_{0,k})}{f(\text{OCV}_{0,k})} \right) = P/\omega_i (A.11) \]

If a straight-line relationship is assumed between \( \text{OCV}(t) \) and \( Q(t) \) such as reported in [15], then \( f(\text{OCV}) \) simplifies to:

\[ \text{OCV}_k(t) = \text{OCV}_{\text{min}} + \frac{(\text{OCV}_{\text{max}} - \text{OCV}_{\text{min}})}{Q_{\text{max}}} Q_k(t) \quad (A.12) \]

Substituting, (A.12) in (A.11) gives the desired \( \omega_i \)

\[ \omega_i = \left( \frac{\sum_{k=1}^{n} V_{\text{batt},k} \frac{f(\text{OCV}_{\text{min}},k) - f(\text{OCV}_{0,k})}{f(\text{OCV}_{0,k})} Q_{\text{max},i}}{\sum_{k=1}^{n} V_{\text{batt},k} \frac{f(\text{OCV}_{\text{min}},k) - f(\text{OCV}_{0,k})}{f(\text{OCV}_{0,k})} Q_{\text{max},i}} \right) \text{discharge} \]

\[ \omega_i = \left( \frac{\sum_{k=1}^{n} V_{\text{batt},k} \frac{f(\text{OCV}_{\text{max}},k) - f(\text{OCV}_{0,k})}{f(\text{OCV}_{0,k})} Q_{\text{max},i}}{\sum_{k=1}^{n} V_{\text{batt},k} \frac{f(\text{OCV}_{\text{max}},k) - f(\text{OCV}_{0,k})}{f(\text{OCV}_{0,k})} Q_{\text{max},i}} \right) \text{charge} \quad (A.13) \]

B. Parameter Estimation

The proposed sharing strategy requires two important parameters: a) initial OCV or SOC \( (\text{OCV}_0) \), b) capacity \( (Q_{\text{max}}) \). The \( \text{OCV}_{0,i} \) in the weighting factor has to be updated at the end of a charging or discharging cycle. The battery capacity \( (Q_{\text{max}}) \) has to be tracked during the operation because long term battery degradations will consequently affect this capacity. Apart from the capacity, the internal impedance \( (Z) \) is also prone to vary with the age and degradations. The variation of that acts as an indicative of power fade because the state-of-health (SOH) of a battery is a combination of power fade and capacity fade as reported in [24] – [25]. Therefore, both the parameters are estimated during the converter operation to track the SOH online.

Impedance \( (Z) \) Estimation:

There are many methods to estimate the impedance of battery; a) a pulse based method [26] b) a ripple based online impedance method similar to [27] as described in Fig A.1. c) EIS based techniques [25]. The pulse power based method is straightforward but it requires the battery to be at rest for at least 2-5 minutes between the tests. This method has been used to find impedance of a battery as part of the pre-characterization tests prior to connecting a battery module to the system. However, it is difficult to provide a pulse current reference externally to the battery modules when the inverter connected energy storage system is providing the necessary grid support because the power command is decided by the inverter which is dependent on the grid side demand. EIS based methods are expensive and are suitable in off-line applications. On the other hand, the ripple based method described in Fig A.1 is valid when the power converter is running because it is based on the ripple part of the voltage and current to estimate the impedance under running conditions. The principle concept is to use the high frequency inductor ripple current of the associated dc-dc converter and corresponding high frequency ripple of the battery terminal voltage to calculate the internal impedance. Therefore, it is deemed more appropriate in this application because this ripple is always present during the converter operation. The switching frequency is in the order of multiples of kHz’s, so it can be assumed that the SOCI/OCV does not change significantly during such small switching interval. Two different equations can be written in each switching period: at \( t = 0 \) and \( t = dT_s \) as shown below (where \( d \) represents the converter duty ratio and the \( \pm \) refers to charging/discharging condition). The ripple part of the voltage and current are extracted through a low pass filter as shown in Fig A.2. The validation of the method is presented in Fig A.2 where an external impedance of 0.033Ω has been put in series with a 24V, 16Ah lead acid battery. It can be seen that the method is able to track the variation of impedance (both increase and decrease within 1 – 2%) and so can be used to track any power fade.

\[ V_{\text{batt}} = \text{OCV} \pm i_{\text{batt}}/Z \text{ at } t = 0 \quad (A.14) \]

\[ V_{\text{batt}} = \text{OCV} \pm i_{\text{batt}}/Z \text{ at } t = dT_s \quad (A.15) \]
Capacity \((Q_{\text{max}})\) Estimation:

\begin{enumerate}
\item Step - 1: Obtain the impedance using the method described above.
\item Step - 2: Find the corresponding OCV using the battery model, i.e. \(OCV = V_{\text{batt}} + i_{\text{batt}}Z\) (discharging) and \(OCV = V_{\text{batt}} - i_{\text{batt}}Z\) (charging).
\item Step - 3: Determine the instantaneous SOC from a pre-characterized and pre-defined SOC-OCV look-up table or a derived function for each battery type.
\item Step - 4: Once the SOC is determined from the \(OCV\), the capacity of each module can be estimated using the following coulomb counting expression similar way as reported in [23]:
\[
SOC(t) = SOC_0 - \frac{\int |i_{\text{batt}}| dt}{Q_{\text{max}}} \rightarrow Q_{\text{max}} = \frac{\int |i_{\text{batt}}| dt}{|SOC(t) - SOC_0|} \quad (A.17)
\]
\end{enumerate}

Moreover, the past researches show that the battery internal impedance \((Z)\) is related to the battery capacity \((Q_{\text{max}})\) either through a linear relationship [24] or through a nonlinear relationship [28]. This means if one parameter changes there will be a subsequent change in the other. Therefore, both power and capacity fade are implicitly included in the formula. The combined SOH could be calculated directly using this method because both the quantities are estimated.

The proposed strategy is valid for various temperature because any variation of temperature causes the capacity \(Q_{\text{max}}\) and impedance \((Z)\) to change because both are functions of temperature [28]. In this work, both are estimated through online monitoring. For example, if the temperature of the modules were to reduce, then the impedance would increase and the capacity would reduce. This will result in a lower current share in the battery using the proposed strategy which would reduce the losses in the battery and help to cool the battery.
