Integrating Systemic Accident Analysis into Patient Safety Incident Investigation Practices

Abstract
There is growing awareness of the limitations of current practice regarding the investigation of patient safety incidents, including a reliance on Root Cause Analysis (RCA) and a lack of safety expertise. Human Factors and Ergonomics (HFE) can offer safety expertise and systemic approaches to incident analysis. However, HFE is underutilised in healthcare. This study aims to explore the integration of HFE systemic accident analysis into current practice. The study compares the processes and outputs of a current practice RCA-based incident analysis and a Systems Theoretic Accident Modelling and Processes (STAMP) analysis on the same medication error incident. The STAMP analysis was undertaken by two HFE researchers with the participation of twenty-one healthcare stakeholders. The STAMP-based approach guided healthcare stakeholders towards consideration of system design issues and remedial actions, going beyond the individual–based remedial actions proposed by the RCA. The study offers insights into how HFE can be integrated into current practice.

Keywords
Patient safety; incident analysis; systemic accident analysis
1 Introduction

High risk industries such as aviation, nuclear, rail and healthcare use accident and incident investigation to learn from failure and create action plans to avoid future incidents (Salmon et al., 2011). Within healthcare there is growing awareness of issues with current practice in incident investigation, with questionable quality of investigations and analysis resulting in ineffective recommendations and action plans (Wu et al., 2008; Peerally et al., 2016; Kellogg et al., 2016). Limitations identified include an over reliance on the promotion of a single flawed reductionist approach, Root Cause Analysis (RCA) and a lack of utilisation of external safety expertise (Wu et al., 2008; Peerally et al., 2016; Kellogg et al., 2016). Human Factors and Ergonomics (HFE) has developed expertise in systems safety and applied various systemic approaches to incident analysis. HFE’s systemic accident analysis and system design approaches have been developed for use in complex work systems (Leveson, 2012; Hollnagel, 2012; Rasmussen, 1997) and are judged to be better suited to forming an understanding of accidents in complex high-risk industries, as compared to traditional causal event chain techniques, such as Root Cause Analysis (Salmon et al., 2011; Leveson, 2004; Hollnagel, 2004).

The potential of systemic accident analysis in healthcare such as Systems-Theoretic Accident Model and Processes (STAMP) (Leveson, 2004), AcciMap (Rasmussen and Svedung, 2000) and Functional Resonance Analysis Method (FRAM) (Hollnagel, 2012) has been demonstrated through analysis undertaken by experienced external method experts (e.g. Leveson et al., 2016; Karsh et al., 2014; Alm and Woltjer, 2010). However, systemic accident analysis has had little exposure to healthcare stakeholders that undertake incident investigations in current healthcare practice. A
potential avenue for HFE to have a beneficial impact on healthcare is by facilitating healthcare stakeholders to apply systems approaches to their incident investigation (Waterson and Catchpole, 2016).

The current study aims to investigate the application of an HFE-led systems approach to healthcare incident analysis. Taking into account the time constraints of healthcare stakeholders the study asks how collaboration between HFE and healthcare can facilitate system thinking and guide analysis towards recommendations of more effective remedial actions.

2 Methods

2.1 Setting

The study is centred on a medication error incident (an insulin overdose case from a prescription error) involving two healthcare providers in the UK serving a population of around one million; an acute trust employing over 14,000 staff with a 900-bed hospital and a trust providing community health services which employs over 5,000 staff. The incident involved a patient being administered an overdose of insulin on three occasions following a drug prescription error. Drug prescription errors have previously been identified as the most common type of medication error (Leape et al., 1995; Bates et al., 1995) and in the UK, it is believed that up to 1.5% of hospital prescriptions may contain a medication error (Dean et al., 2002).

The events leading up to the incident can be summarised as: A patient was admitted to a hospital emergency department following a fall at home and subsequently transferred between wards. After being found to have high blood glucose level a review by a diabetes specialist nurse (DSN) suggested the patient to start insulin
glargine U100 10 units once per day. The recommended dosage was misread by the prescribing doctor and 100 units were prescribed instead of 10 units. The high dosage was administered twice at one provider ward and then following discharge to another provider ward, a further time before the error was identified by an advanced nurse practitioner.

2.2 Incident analysis: current practice

Prior to this study, a formal investigation of this incident was undertaken through Root Cause Analysis by a team of healthcare professionals following the National Patient Safety Agency (NPSA) level one investigation profile (NPSA, 2008): Level one is a most commonly used concise investigation for incidents that resulted in no, low or moderate harm to the patient. This investigation team included an investigation chair, 2 team leads and 7 team members. Information gathered by this team included interviews with key staff involved in the incident, statements from nursing and medical staff involved in the incident, a review of an incident report form, review of medical and nursing records, and review of procedures and protocols. The report from this investigation was subsequently used as the initial basis for the systemic accident analysis and the results from both analyses were compared.

2.3 Systemic accident analysis

Based on the RCA-based investigation report, a systemic accident analysis approach using Systems Theoretic Accident Modelling and Processes (STAMP) (Leveson, 2012) was applied through two healthcare stakeholder workshops facilitated by two Human Factors and Ergonomics (HFE) researchers with the following profiles:
1. Junior HFE researcher, a graduate member of the Chartered Institute of Ergonomics and Human Factors (CIEHF) whom had previously graduated from an MSc in Ergonomics and Human Factors, currently PhD researcher on healthcare systems ergonomics. This researcher acted as the main facilitator and analyst.

2. Senior HFE researcher, a Chartered Ergonomist and Human Factors specialist and Lecturer in systems HFE with 14-year research experience in healthcare ergonomics. This researcher oversaw and supervised the analysis.

The two HFE researchers conducted an initial STAMP-based incident analysis based on the data from the RCA report. The STAMP approach was chosen due to its application of systems theory and detailed analysis of the behaviour shaping mechanisms in the decision-making of individuals. This has been shown to be a powerful combination in understanding why an accident happened and how to best design remedial actions to prevent future occurrence, with some evidence of successful use in a healthcare context (Leveson et al., 2016).

STAMP describes an accident in terms of a hierarchy of control based on adaptive feedback mechanisms and models the hierarchical safety control structure present in the system to enforce safety constraints (Leveson, 2012). This type of approach to accident analysis aims to overcome the limitations in explaining accidents in terms of events, acts and errors (Leveson, 2012; Hollnagel, 2012; Rasmussen, 1997; Rasmussen et al., 1990). A general example of a safety control structure model is adapted for hospital application and provided in Figure 1. The control structure contains downwards arrows showing a reference channel with the information necessary to impose safety constraints on the level below and upwards arrows that
show the measuring channel with feedback returned up the hierarchy on how effectively constraints are being satisfied (Leveson, 2015).

![Diagram of generic safety control structure for hospital. Adapted from Leveson, 2004](image)

The process of applying STAMP to accident analysis is described fully elsewhere (Leveson, 2012), here it is simplified and summarised into the following eight steps:

1. Identify the system and hazard involved in the incident
2. Identify the safety-related constraints and responsibilities, associated with that incident
3. Document the safety control structure in place to enforce the safety constraints and control the hazard

4. Determine the proximate events leading to the incident and analyse the frontline operations present at the lower level of the control structure

5. Analyse the higher levels of the control structure determining how and why these managerial levels contributed to the inadequate control of the hazard

6. Examine overall coordination and communication issues between controllers that could have contributed to the incident

7. Determine any changes and weakening in the control structure that occurred over time and contributed to the incident

8. Generate recommendations for remedial action and strengthening of the safety control structure (Leveson, 2012)

The application of STAMP in this study contained several stages and these are summarised in Table 1 with detail on the people involved and the time taken to complete. Two HFE researchers carried out step 1-3 prior to step 4-8, which were carried out with healthcare staff.

For step 1-3, two HFE researchers carried out the reanalysis of the RCA report using STAMP. The two researchers created a draft safety control structure model to be utilised in the subsequent healthcare stakeholder workshops.

### 2.4 Workshops

This study aimed to involve healthcare stakeholders in the systemic accident analysis with facilitation by external HFE researchers, since it is imperative to involve them to act as subject matter experts to validate STAMP’s system models (Hettinger et al., 2015) and develop more relevant and effective recommendations for change. This was done through two workshops; the workshops introduced accident analysis concepts and the STAMP approach presented by an HFE researcher. Following the introduction, the safety control structure system model was provided to the participants and they were invited to take part in the analysis using a step-by-step method guide. The first workshop aimed to develop recommendations for remedial action, in addition to this the second workshop aimed to evaluate the utility and usability of STAMP with feedback from the original RCA investigation team.
2.4.1 Workshop 1

The first workshop was 3 hours in duration with 18 attendees from healthcare including members of local commissioning groups, patient safety managers, front line staff and patient representatives, facilitated by 3 HFE researchers. All of the participants were from the same regional healthcare where the incident occurred, but none of them were involved in the original RCA investigation. Following the introduction to STAMP the participants were asked to participate in the incident analysis, working in 3 separate groups each with a safety control structure system model, method guide and facilitation by an HFE researcher.

2.4.2 Workshop 2

The second workshop was 2 hours in duration and facilitated by the 2 HFE researchers. The workshop was attended by 4 healthcare professionals (with an average of 31 years healthcare experience), including 3 involved in the original RCA investigation. During this workshop, following the presentation of the concepts of STAMP, the safety control structure system model was validated and the participants were invited to contribute to the analysis, using the model and STAMP concepts as discussion points. At the end of the workshop the participants were asked to give feedback on the utility and usability of the STAMP approach. This workshop was audio-recorded.
3 Results

3.1 Processes – Comparison between HFE-led STAMP and current practice RCA

Key information from the RCA and STAMP processes is presented in Table 2. Along with the different analysis methods used, there were differences in the people involved, their areas of expertise and the approach to group work. The timescales set for completion of the investigation in the UK policy is 60 working days including 15 days for internal governance approval. The actual time taken for the RCA process for this case was not recorded, but the team usually carry out investigation whilst still holding their clinical case load. A comparison of the time taken for each approach isn’t made but the HFE-led analysis required an additional 26 working hours by HFE experts to the previously completed investigation.

The RCA investigation was led by two Patient Safety Coordinators with a team of seven clinical staff and chaired by an Assistant Chief Nurse. The RCA used data from interviews and documentation which was analysed using time line, fishbone diagram and incident decision tree tools. This process can be described as predominantly work domain expertise led, using a linear cause effect analysis model.

In contrast, the STAMP process was led by HFE expertise, with the facilitated participation of work domain experts through workshops, using a systemic accident analysis model.

### 3.2 Outputs - Comparison between HFE-led STAMP and current practice RCA

The RCA identified a root cause in the prescription error by the doctor following misinterpretation of the specialist nurse recommendation, stated as human error. Incorrect dose administration by the nurses was also identified as a service/care problem. These two issues were then the subject of further analysis using the incident decision tree and fishbone diagram.

The RCA approach uses a contributory factors classification framework (NPSA, 2009) and maps identified factors to an Ishikawa fishbone diagram (Ishikawa, 1982; NPSA, 2016) as seen in Figure 2. The classification framework encourages identification of contributory factors from an individual to organisational level and presents these in list form.
The RCA can be contrasted with the STAMP approach where a qualitative model of the system is formed which includes modelling relationships and interactions between system components through control-feedback loops, as shown in Figure 3.
Figure 3 Safety control structure for insulin prescription and administration (simplified for readability)

STAMP’s safety control structure model is used to identify weaknesses in the control structure and control-feedback flaws. STAMP considers four types of hazardous control actions (Leveson, 2012):

i. Control actions necessary to enforce safety constraint are not given (control action not given)

ii. The necessary control actions were provided too early or too late (incorrect timing)

iii. Unsafe control actions were provided (unsafe control action given)

iv. Control action stops too soon or is applied too long (incorrect duration)

STAMP also analyses the behavioural shaping mechanisms for decision-making of the actors within that system in terms of a process or mental model. This being the
actor’s understanding of current system status which needs to be regularly updated. The mental model of a decision maker can be incorrect due to poor feedback and incorrect information about system status as illustrated in Figure 4. The identified control flaws are compared with the contributory factors identified by the RCA in Table 3.

<th>STAMP identified control flaws</th>
</tr>
</thead>
</table>
| Diabetes specialist nurse    | Ambiguity in the recommendations in terms of written clarity                                          | **Control flaw:** Issue in communication and coordination with prescribing doctor  
**Mental model:** Recommendation correctly interpreted and correct prescription made  
**Feedback flaw:** No feedback post recommendation                                                                                                        |
| Doctor (hospital)            | Patient: Altered neurology, poor history of diabetes compliance. IV steroids falsely elevated blood glucose  
**Task:** New prescription should trigger check of dose  
**Communication:** Misread prescription  
**Team:** Advice written on form was unclear  
**Training:** Insulin e-learning not mandatory  
**Working condition:** Not doctor's base ward  
**Equipment:** Glargine available in different strengths                                               | **Control actions not given:** Doctor did not question high recommended dosage or review suggestion thoroughly  
**Mental model:** Incorrect understanding of patient status and required prescription  
**Feedback flaw:** Coordination and communication issue in handwritten notes and lack of face-to-face handover at time of writing prescription  
No feedback after prescription made                                                                                                                        |
| Nurse (hospital)             | Individual: Both nurses in post for 12 months or less with no previous competency issues             | **Control action not given:** Nurse did not query the dosage except for with peers and did not cross-check with specialist nurse documentation or patient notes  
**Mental model:** Accepted doctor's prescription as correct. Nurses recognised prescription as a large dose but they had seen large doses of insulin prescribed before  
**Feedback flaw:** The charts readily available to ward nurses had high dosage on them. The nurse questioned between themselves but not to specialist nurse or senior staff                                                                 |
| Pharmacy (hospital)          | Missed opportunity to identify the error when prescription checked prior to the patient being transferred | **Control action not given:** Pharmacy did not cross-check prescription against patient records (medication stock was on ward). Prescription was checked prior to patient being transferred but issue not identified  
**Mental model:** Prescription is appropriate                                                                                                             |
| Organisational (hospital)    | Insulin safety identified as a high priority and implementation of a new safety strategy has begun  
A team of specialist diabetes nurses has been established                                               | **Control action provided too late:** Assessment form documentation not in format currently advised. Not updated until triggered by incident                                                                                   |
| Nurse (Community)            | Previous administration of dose and discharge documentation provided rationale for nurse to administer dosage | **Control action not given:** Nurse did not query the dosage reported by peers  
**Mental model:** Accepted prescription as correct  
**Feedback flaw:** Medication dosage had been administered twice previously and on discharge documentation                                                  |
The RCA focused on the hospital doctor and nurses and the factors contributing to their involvement in the incorrect prescription and administration. The use of an incident decision tree tool, that seeks to determine the actor’s intention and blameworthiness of human error (Reason, 1997; Meadows et al., 2005), absolves those actors of blame, but this focus means less attention is paid to other areas of the system, as shown in Table 3.

A major difference between RCA and STAMP is in STAMP’s modelling of the system. RCA does not model the relationships between system components and it does not build a model of the system. Contributory factors are attached to the identified service problem and presented in list form, whereas the control-feedback relationships presented in STAMP’s safety control structure provide analysis of interactions within the system.

Another major difference is in STAMP’s explicit consideration of both the system operation and the system development or design as shown in Figure 1. The consideration of system design led the analysis to question the change management processes regarding specification, design, evaluation and approval of new information templates/forms to be used in a hospital. There was also questioning about the design of information systems, with information given to the prescribing doctor split between electronic and paper format.

### 3.3 Recommendations

Both analyses produced recommendations to prevent future incidents, with a summary of these presented in Table 4. In comparing the analyses recommendations, STAMP generated additional recommendations for system-level improvement, especially with
consideration that two system-level improvements from RCA referred to the initiatives which were already being conducted prior to the incident: i) the review and implementation of the new diabetes assessment form; ii) the implementation of insulin strategy. The RCA-based recommendations focussed on staff training and personal reflection, whereas the STAMP analysis broadened the discussion and recommendations to systemic issues (service development and change management), rather than just the operation management issues.

### 3.4 HFE analysis workshop participant feedback

The HFE researchers were not qualified healthcare professionals with the healthcare stakeholders played a vital role in providing work domain knowledge. The healthcare stakeholders contributed to the analysis and generation of recommendations. Feedback on the STAMP approach from the participants of the second workshop was generally positive; with all 4 participants agreeing that STAMP was useful in learning from the incident and that they would make additional recommendations based on the approach.

The participants found the approach helped them think about the incident in a systemic way as shown in the following quotes by those who were involved in the original RCA investigation.

‘The approach enables us to think more broadly about system controls and failure points’

‘Previously I felt my team were really to blame, but now I understand it was multifactorial’

‘It made me think of the interactions between people. All the groups/individuals involved’
On future application, all of them indicated that further experience with the method and HFE experts’ help would be required.

4 Discussion

This study has applied an HFE-led systemic accident analysis approach to healthcare incident analysis and demonstrated STAMP’s potential in healthcare. The use of STAMP and collaboration between HFE and healthcare stakeholders was found to facilitate systems thinking, impacting the thinking of some of the original investigators of the incident and guided the development of underlying system-based recommendations.

4.1 Current practice and benefit of HFE input

Although the HFE-led systemic accident analysis approach has proven useful, it is difficult to determine how much of the observed effect on analysis outcomes was due to the use of STAMP and how much was due to the presence and facilitation of HFE practitioners in the present study. The lack of knowledge about STAMP in healthcare meant the healthcare investigators were not capable of using it alone and it is assumed both HFE practitioner presence and use of a different accident model in STAMP contributed to the effect on analysis outcome. Previous research has suggested accident investigation and incident analysis can be influenced by several factors including the background and knowledge of the analyst (Rasmussen et al., 1990; Lundberg et al., 2010), the accident model used (Lundberg et al., 2009), the time and resources available for the investigation and proposed remedial actions being constrained by practical considerations (Lundberg et al., 2010).
Within this case study, groups with different backgrounds have taken part in the incident analysis; Healthcare stakeholders with specialist knowledge on the work domain and HFE researchers with HFE knowledge. Work domain knowledge is a vital part of the analysis and already seen as such, here it is argued that HFE knowledge is also a vital component for good quality analysis outcomes. With neither group of analysts holding the requisite knowledge from both domains a collaboration was needed. This collaboration has its challenges such as the limited time healthcare stakeholders can give and communication between the two professional groups with their different technical terms and jargon.

In this study, the healthcare stakeholders were exposed to a specialist systemic accident analysis technique which is considered a difficult approach to use even by experienced investigators (Underwood et al., 2016). The healthcare stakeholders contributed to the systemic analysis but felt they would need support and further experience to apply the approach in future. On reflection, the facilitation by HFE experts can be more effective if focus is on the main thinking behind the systems approach rather than spending too much time on the details of STAMP, especially with time constraints considered.

The use of a systemic accident model on top of the RCA cause-effect model will also influence the analysis outcome (Hollnagel, 2006; Lundberg et al., 2009). STAMP contains a combination of systemic thinking with qualitative systems modelling and detailed analysis of human decision making. While RCA included identification of contributory factors to incidents it lacked a description or explanation of the relationships and interactions between humans and components across the system. With
contributory factors presented in list form rather than providing efforts of system modelling. This limits the understanding of how these factors impacted on human decision making. The increased understanding of relationships and mechanisms formed in STAMP is shown to be of benefit to the development of remedial actions.

4.2 Proposed remedial actions

The initial healthcare staff led RCA analysis produced outcomes and remedies consistent with previous RCA investigations for drug error, with outcomes commonly reliant on staff education, which is reported as being a weak remedy in addressing adverse events (Mills et al., 2008). The HFE-led systemic analysis in this case proposed remedial actions to address system level issues, such as change management in service development.

Consideration of the time it takes to undertake an investigation and the healthcare stakeholder time used up in the analysis is always prominent. Certainly, the HFE systemic analysis brought up questions that could be further analysed if time allowed. For example, the role of the pharmacy in checking the prescription which was only touched on.

The type of remedial actions proposed and implemented after incident investigations are not only influenced by what is found in the analysis. Research involving interviews with investigators from multiple industries, including healthcare, has shown remedial actions are dependent on several factors including: what the analyst/organisation knows how to fix; if the remedies are possible to fix and under control of the organisation; and cost-benefit balance (Lundberg et al., 2010). The commonly proposed healthcare
remedial actions of staff training and small policy change (Kellogg et al., 2016) are likely to be proposed due to the organisation knowing how to implement them, being under the control of the organisation and being easier (and cheaper) to implement than deep systemic issues. Indeed, many of the remedies suggested by the STAMP analysis would need further understanding and specification prior to implementation. Remedies such as changes to computerised systems are a serious undertaking, which may make analysts reluctant to propose this type of recommendation. Immediate actions might not be possible for such system-based interventions, but healthcare organisations can accumulate an evidence base for future changes, so they need to welcome and encourage proposals for system changes to be undertaken over the long-term, alongside quick fix remedial actions.

4.3 Integrating HFE in healthcare incident analysis

The addition of HFE input in this study took less than a working week of the HFE researchers’ time, and two to three hours for each individual healthcare stakeholder participant. The HFE expertise can be utilised throughout the whole investigation process, but can also be tapped at the last stage of analysis and recommendation development as demonstrated in this study. The major obstacle could be to get relevant healthcare stakeholders in the same location, at the same time, for the two to three hours needed for the workshops as we experienced in this study.

Systemic analysis can be effectively used to conduct analyses on batches of similar incidents. Leveson, et al (2016) used 30 adverse cardiovascular surgery events using one safety control structure with various control flaws from all incidents overlaid. This both increases the quality of the analysis through the additional data and cuts the time
taken for each individual analysis. Although slowing the response to each individual incident these would be actioned through initial RCA analysis, with the HFE analysis providing a review process. In this way, HFE expertise can be effectively utilised in collaboration with healthcare professionals.

5 Conclusions and future research

The present study raises the possibility that HFE expert-facilitated systemic accident analysis with healthcare stakeholders can enable effective and efficient patient safety incident investigation identifying remedial actions on underlying system issues beyond individual issues. This study offers insights into how human factors expertise and approach can be integrated into patient safety incident investigation practice.

This study is limited in having a single case study design, multiple case studies would improve generalisability. HFE practitioners could assist at organisational and/or regional level. Currently within UK healthcare serious incident reports are reviewed/approved at regional level by patient safety managers and HFE practitioner involvement could occur at this juncture. However, it is also possible that the ability to influence safety practice could be strengthened by working closely with healthcare providers through the collaborative incident investigation at organisational level. Research would also benefit from following the case through to implementation of change, which was not possible in this study.
Future studies would also benefit from multiple incident analysis and increased numbers of participants evaluating systemic approaches for usability and utility in different healthcare contexts and settings.

6 Acknowledgements

The authors would like to thank Leicestershire Improvement, Innovation and Patient Safety Unit (LIIPS) for their support in organising the workshops and the workshop participants for their inputs. We also would like to thank Dr Diane Ketley for her comments on the paper.
