Abstract

The fracture toughness property ($K_{IC}$) of Si$_3$N$_4$ and ZrO$_2$ engineering ceramics was investigated by means of CO$_2$ and a fibre laser surface treatment. Near surface modifications in the hardness was investigated by employing the Vickers indentation method. Crack lengths and geometry were then measured by using the optical. A coordinate measuring machine was used to investigate the diamond indentations and to measure the lengths of the cracks. Thereafter, computational and analytical methods were employed to determine the $K_{IC}$. An increase in the $K_{IC}$ of both ceramics was found by the CO$_2$ and the fibre laser surface treatment in comparison to the as-received surfaces. The $K_{IC}$ of the CO$_2$ laser radiated surface of the Si$_3$N$_4$ was over 3% higher in comparison to that of the fibre laser treated surface. This was by softening of the near surface layer of the Si$_3$N$_4$ which comprised of lower in hardness, which in turn increased the crack resistance. The effects were not similar with the ZrO$_2$ ceramic to that of the Si$_3$N$_4$ as the fibre laser radiation in this case had produced a rise of 34% compared to that of the CO$_2$ laser radiation. This occurred due to propagation of lower crack resulting from the Vickers indentation test during the fibre laser surface treatment which inherently affected the end $K_{IC}$ though an induced compressive stress layer. The $K_{IC}$ modification of the two ceramics treated by the CO$_2$ and the fibre laser was also believed to be influenced by the different laser wavelength and its absorption coefficient, the beam delivery system as well as the differences in the brightness of the two lasers used.

**Keywords:** CO$_2$ laser, Fibre laser, Si$_3$N$_4$ and ZrO$_2$ engineering ceramics, Vickers indentation method, $K_{IC}$.
1.0. Introduction

Low crack resistance and fracture toughness in comparison to metals can limit the use of ZrO₂ and Si₃N₄ engineering ceramics, particularly for demanding applications. In any case, the applications of ZrO₂ and Si₃N₄ have gradually increased on account of the desirable physical properties and longer functional life which often gives the engineering ceramics a commercial advantage over the conventional materials in use. Conventional metals and alloys especially can be replaced by engineering ceramics such as ZrO₂ and Si₃N₄ due to its exceptional mechanical and thermal properties offered. Now, ZrO₂ and Si₃N₄ ceramics in particular are predominantly being used to manufacture components in the aerospace, automotive and motorsports industrial sectors. For such applications, fracture toughness is an essential property since low fracture toughness in comparison to metals and alloys is one of the disadvantages of the ceramic. Inherently, an increase in the fracture toughness would therefore, lead to an enhancement in the components functional life, better performance which in turn leads to reduction in the maintenance time and cost of the component/part and or the system.

Fracture toughness is considered to be an important property for both of the ZrO₂ and the Si₃N₄ as well as other ceramics in general due to their high hardness and brittleness. Materials such as metals and alloys are soft and ductile which in turn would resist cracks at higher stress levels and loading [1, 2-4], whereas hard and brittle materials such as a Si₃N₄ ceramic posses a low fracture toughness and allow crack propagation to occur at lower stresses and loading. The fracture toughness for the ZrO₂ ceramic is fairly high in comparison to the Si₃N₄ but not in comparison to metals and alloys. This is due to their low ductility, high hardness, caused by the closely packed grains along
with a porous structure which increases the crack-sensitivity. This characteristically prevents these ceramics from increasing the movement of dislocations in comparison to that of metals [5-6]. Dislocations are hard to generate within the ceramics due to its strong and highly directional covalent bonds which make it difficult to move the atoms from its lattice positions. Mechanical yielding of the ZrO_2 or the Si_3N_4 is also limited due to the porosity and the surface flaws make it crack-sensitive and eventually lead to a much lower resistance to fracture. K_{1c} is a parameter of fracture toughness and is low for both the ceramics in comparison with metals and alloys so it would be an advantage if the K_{1c} of the ceramic is enhanced. Through improvement of K_{1c}, it is possible to make way for new applications where metals and metal alloys fail due to their low hardness, thermal resistance, co-efficient of friction and wear rate.

This paper investigated the use of empirical equations from the literature to calculate the fracture toughness property (K_{1c}) of a ZrO_2 and a Si_3N_4 engineering ceramic and observed the effects thereon of the CO_2 and the fibre laser surface treatment. A change in the K_{1c} has an influence on the materials functionality or diversity to its applications, by improving the K_{1c} of materials can enhance its functional capabilities such as longer functional life, improved performance under higher cyclic and mechanical loading particularly for demanding applications as previously mentioned.

Laser processing of ceramic based materials has been the subject of many investigations. Malshe et al. [7] investigated the CO_2 laser processing of a Si_3N_4 ceramic to eliminate imperfections within the ceramic and further conducted a three-point bending strength study of the Si_3N_4 after the CO_2 laser surface treatment. Sun Li et al. [8] then investigated that an YSiAlON phase within the Si_3N_4 was softened through melting and filled the pre-existing fractures to increase the flexural and the
bending strength. A similar investigation was also conducted by Segall et al. [9] by using a high powered CO$_2$ laser to cover a fractured surface of a thin film Al$_2$O$_3$ ceramic sheet. Nd:YAG laser machining of structural ceramics was demonstrated by Anoop et al. [10] and discussed the physical phenomenon of material removal of Al$_2$O$_3$, SiC, MgO and Si$_3$N$_4$ ceramics. The use of Nd:YAG laser was also employed by Hae and Lawrence [11] on MgO–PSZ ceramics to improve the wettability characteristics for biomedical applications. Hae and Lawrence [12] also investigated the improvement of cell adhesion through a CO$_2$ laser surface treatment. Hae and Lawrence [13] in another investigation used a finite element model (FEM) and compared it to an experimental model to simulate the CO$_2$ laser surface treatment of the MgO–PSZ. Several other studies discussed the use of industrial lasers to modify the surface of engineering, structural and refractory type ceramics [14 - 19]. Triantafyllidis et al. [14] investigated a possibility of achieving a crack-free surface of a refractory Al$_2$O$_3$ ceramics using double laser sources: a CO$_2$ and a high powered diode laser (HPDL) by balancing out the thermal gradient and increasing the solidification rate. Investigation by Lawrence and Li [15] initially employed a CO$_2$ laser; a Nd:YAG laser; a HPDL and an excimer laser with a SiO$_2$/Al$_2$O$_3$ ceramic to study the effect of the laser beam absorption on the ceramic and showed that the CO$_2$ laser had the highest absorption followed by the Nd:YAG and then the HPDL. Lawrence and Li [16] then employed a high powered diode laser (HPDL) to surface treat Al$_2$O$_3$ based refractory ceramic and achieved an increased wear life as a dense structure comprising of minor cracks and porosities were found. Another investigation by Lawrence and Li [17] also used the HPDL to process an ordinary Portland concrete (OPC) and showed enhancement in the resistance to chemical attack, water absorption as well as improved wear life of the OPC. Wang et al. [18, 19] published two separate papers on the microstructural and surface density modification of a mixture of Al$_2$O$_3$ + ZrO$_2$ + SiO$_2$
refractory ceramics system from employing the CO₂ laser to show that the laser
treatment had refined the microstructure into a fine grain dendrites structure as well as
achieving a change in its phase transformation.

Much work has been conducted by using the CO₂, Nd:YAG, HPDL and an excimer to
process various technical ceramics. However, no other investigation except the one of
Shukla and Lawrence [20, 21] has been done hitherto by employing a fibre laser to
process engineering ceramics. Moreover, the fibre laser was selected because of its
shorter wavelength radiation in comparison to the conventional lasers previously used
for ceramic processing [7-22]. Also the section of the CO₂ laser was made so a contrast
of two different wavelengths can be seen. It would be interesting to investigate further
the effect of short wavelength on the surface properties of the ZrO₂ and Si₃N₄
engineering ceramic. Moreover, Shukla and Lawrence [20-21] investigated the effects
on the K₁c using a fibre laser to surface treat a ZrO₂ and Si₃N₄ engineering ceramics
which showed changes in the K₁c of the both ceramics. However, the effects of the
fibre laser are different to that of the CO₂ laser due to the differing wavelength, beam
conditions as well as the beam delivery system despite applying identical parameters.
This is why a broader investigation was carried out by using the CO₂ and the fibre laser
on the ZrO₂ and the Si₃N₄ engineering ceramic. Furthermore, despite the Nd:YAG laser
wavelength being in the same region as that of the fibre laser, the Nd:YAG laser does
not function stably in the continuous wave (CW) mode. This is required for reducing
the thermal shock induced into a ceramic. Fibre lasers also produces high brightness in
comparison to the more conventional CO₂ and Nd:YAG lasers which generally inhibits
deeper penetration, capability of producing finer spot sizes, longer depth of focus, as
well as low cost per wattage being exhibited due to it high brightness. As one can see,
this investigation is timely as limited research has been conducted by employing fibre
lasers to conduct the surface treatment of materials, particularly for engineering ceramics.

2.0. Background of the Vickers indentation method to determine the $K_{1C}$ of the ceramics

The Vickers indentation test can be used to determine the $K_{1C}$ of ceramics and glass type materials from empirical relationships as demonstrated in [1, 2, 4, 23 - 25]. The procedure and steps in order to produce a genuine Vickers indentation test was followed and is documented elsewhere [26]. Several authors have used this method to determine the $K_{1C}$ of ceramics and glass type materials [3, 4, 20, 21, 27, 28]. Ponton and Rawlings [3, 4] Chicot et al. [24], Liang et al. [25], Orange et al. [28] presented a thorough investigation into various equations specifically applied to ceramics and justified the reasons for their suitability for use. The equations originate from various other authors [27, 29-38] and are said to be unique for various ceramics and glass based materials. However, due to simplicity and ease of use, equations derived by Ponton and Rawlings were adopted for this investigation.

3.0. Experimentation Technique and Analysis

3.1. Background of the test materials

The materials used for this work was a Cold Isostatic Pressed (CIP) Si$_3$N$_4$ with (90% Si$_3$N$_4$, 4% Yttria, 4% Al$_2$O$_3$ (alumina) and 2% other unspecified content by the manufacturer) and ZrO$_2$ with (95 % ZrO$_2$ and 5 % Yttria). Each test piece was 10 mm x 10 mm x 50 mm bars and comprised the surface roughness of 1.56$\mu$m (Si$_3$N$_4$) and 1.58$\mu$m (ZrO$_2$) ceramics as provided by the manufacturer (Tensky International Company Ltd; Taiwan). This was to minimize the beam reflection as shinier surfaces
would reduce beam absorption, although, rougher surfaces of the ceramics can often be more prone to cracking in comparison [1, 39]. The experiments were conducted in ambient condition at a known atmospheric temperature (20°C). All surfaces of both the Si$_3$N$_4$ and ZrO$_2$ engineering ceramics to be treated were marked with black ink prior to the laser treatment to enhance the absorption and allow the laser beam to further penetrate into the surface. Initial experiments reviewed that the black ink helped the beam to absorb better into the material. This was particularly the case with the ZrO$_2$ ceramic as it reflected the beam without the black ink because of its colour being white. Furthermore, it was necessary to conduct like by like experiments with both lasers types using identical material surface conditions so a true comparison of the effects of the two lasers can then be further performed. The back ink was generally removed by the CO$_2$ or the fibre laser surface treatment and was not found to have any further effect on the ceramics after the laser surface interaction had taken place.

### 3.2. Vickers indentation test

An indenter of a specific shape made from a diamond material was used to indent the CO$_2$ and the fibre laser treated surfaces of the Si$_3$N$_4$ and the ZrO$_2$ engineering ceramics. Around 50 indentation tests each were performed on all surfaces examined. An indentation load of 49.05 N was used. The indented surface and the resulting crack lengths were measured using the optical microscopy and a co-ordinate measuring machine. A standardized technique was adopted to ensure that a valid indentation tests were performed [26]. Thereafter, the surface area of the indentation (diamond footprint) was placed into Equation 1 to calculate the hardness value:

\[
HV = \frac{2P \sin \theta/2}{D^2} = 1.8544P/D^2 \tag{1}
\]
where, \( P \) is the applied load, \( D \) is the average diagonal size of the indentation and \( \theta \) is the angle between the opposite faces of the diamond indenter.

### 3.3. Calculation of the \( K_{IC} \)

The equation used to determine the \( K_{IC} \) in this work was chosen by taking in consideration of the findings in a previous investigation by Shukla and Lawrence [20], which revealed that Palmqvist cracks were produced followed by a propagation of the median half-penny cracks when applying a high indentation loads to the as-received surface of the ceramics. Furthermore, the values produced by this equation was 38% accurate for the \( \text{Si}_3\text{N}_4 \) and 42% for the \( \text{ZrO}_2 \) in obtaining the true \( K_{IC} \) values which is usually between 4 to 8 MPa m\(^{1/2}\) for the \( \text{Si}_3\text{N}_4 \) and 8 to 12 MPa m\(^{1/2}\) for the \( \text{ZrO}_2 \) ceramic. Equation 2 was hence used based on these finding to calculate the \( K_{IC} \) of all laser treated ceramic samples in this study.

\[
K_{IC} = 0.016 \left(\frac{E}{HV}\right)^{1/2} \left(\frac{P}{c^{3/2}}\right) \tag{3}
\]

Where, \( P \) is the load; \( c \) is crack length; \( HV \) is the Vickers material hardness value; \( E \) is Young’s modulus (320 GPa for the \( \text{Si}_3\text{N}_4 \) and 210 GPa for the \( \text{ZrO}_2 \)) and 0.016 is the materials empirical value [3, 4]. The hardness obtained from the Vickers indentations test and the crack length of the ceramics after the Vickers indentation test were the changing input parameters for Equation (2).

### 3.4. \( \text{CO}_2 \) laser surface treatment

A 1.5 kW \( \text{CO}_2 \) laser (Everlase S48; Coherent, Ltd.) emitting at a wavelength of 10.6 \( \mu \text{m} \) in the continuous wave (CW) mode was used in this work. The processing gas used was compressed air, at a flow rate of 25 litre/min. To obtain an operating window,
trials were conducted by varying the power between 50 to 200 W and varying the traverse speed between 100 and 600 mm/min. From these trials it was found that 65 W at 600 mm min/min for ZrO$_2$ and 175 W at 100 mm/min for Si$_3$N$_4$ were the ideal laser parameter to use in terms of achieving a crack-free surface. Stand-off distance between the nozzle and the work-piece was kept to 16 mm in order to obtain a focal spot size of 3 mm. Programming of the laser was conducted using an integrated software which controlled the motion system. A 50 mm line was programmed using numerical control (NC) programming as a potential beam path which was transferred by a .dxf file.

3.5. Fibre laser surface treatment

A 200 W fibre laser (SP-200c-002; SPI, Ltd.) was employed which emitted a continuous wave (CW) mode beam at a wavelength of 1.075 µm. The processing gas used was compressed air and was supplied at a flow rate of 25 litre/min. To obtain an operating window, trials were conducted at a fixed spot size of 3 mm and by varying the power between 25 and 200 W, as well as varying the traverse speed between 25 and 500 mm/min. From these trials, it was found that 143 W at 100 mm/min for the ZrO$_2$ and 200 W at 100 mm/min for the Si$_3$N$_4$ were the ideal laser parameter to use in terms of achieving a crack-free surface. A 50 mm line was also programmed using NC programming as a potential beam path which was transferred by a .dxf file.
4.0. Results and Discussion

4.1. Comparison of CO$_2$ laser surface treatment with fibre laser surface treatment of the ZrO$_2$ engineering ceramic

4.1.1 Change in the surface hardness

Figure 3 presents the fluctuations in the hardness of the CO$_2$ and the fibre laser radiated surfaces of the ZrO$_2$ ceramics along with its mean hardness value over 50 indentation tests that were conducted on one surface plane. As one can see that the hardness of the CO$_2$ laser radiated surfaces was considerably lower than that of the fibre laser radiated surface. The average hardness of the CO$_2$ laser radiated ZrO$_2$ was 854 HV with the highest value being 1120 HV and the lowest being 473 HV. The average hardness for the fibre laser radiated surface of the ZrO$_2$ was 940 HV. The highest value above the mean was 1089 HV and the lowest being 826 HV for the ZrO$_2$ ceramic. The hardness values fluctuated in both of the curves due to an uneven surface being produced from material removal as well as melting and solidification. The hardness of the CO$_2$ laser radiated surface was up to 22% lower than that of the fibre laser. This showed that the CO$_2$ laser radiation had softened the surface of the ZrO$_2$ in comparison to that of the fibre laser radiated surface.

4.1.2. Change in the crack length

Average crack length of the CO$_2$ laser treated surfaces was 216$\mu$m with the highest value above the mean being 333$\mu$m and the lowest being 143$\mu$m as presented in Figure 4. The average crack length of the fibre laser radiated surface of the ZrO$_2$ was 171$\mu$m. The crack length was much reduced in comparison with the crack length of the CO$_2$ laser radiated surfaces. Despite the increase in hardness produced by the fibre laser radiated surface, a 21% decrease in crack length was found from the fibre laser
radiation. This can be seen from Figure 5 and Figure 6 where the diamond indentation produced by the CO₂ laser radiation (see Figure 5) was larger due to the softening of the surface but produced high cracking profiles. In comparison, the indentation created by the fibre laser radiated surface was smaller due to surface hardening and yet produced a considerably smaller cracking geometry. The expected result was larger crack length due to smaller indentation foot-print produced. From this, it can be postulated that compressive residual stress could have been induced during the fibre laser surface radiation which caused lower crack propagation as further explained in section 4.3.

One can see from the optical micrographs in Figure 5 and Figure 6 that surface oxidation is not apparent. The ZrO₂ ceramic is less sensitive to the effect of surface oxidation during the exposure to the laser beam radiation due to the majority of the ZrO₂ ceramics comprising of Zr + O₂. It can also be seen from the optical micrographs that the ZrO₂ has been changed in colour especially in Figure 5 due to the thermal energy being induced. It is possible however, that the ZrO₂ had undergone a degree of compositional change since it has been exposed to the environment at high temperatures during both CO₂ and the fibre laser irradiation. A compositional change from ZrO₂ to ZrCO₂ is likely to have occurred during the laser surface interaction. This would bring changes in the fracture resistance of the ZrO₂ and is deemed to have influenced the K₁C values after the laser surface treatments.

4.1.3. Change in the surface K₁C

Figure 7 presents the K₁C of the CO₂ and the fibre laser treated ZrO₂ ceramics which showed that the K₁C of the fibre laser radiated surfaces was 29% higher than that of the CO₂ laser radiated surface. The average K₁C of the CO₂ laser radiated surface of the
ZrO₂ was 5.63 MPa m¹/² with the highest value being 9.85 MPa m¹/² above the mean and the lowest being 2.97 MPa m¹/² below the mean. The average value found for the CO₂ laser radiated surface of the ZrO₂ was 4.16 MPa m¹/² with the highest value being 7.54 MPa m¹/² and the lowest being 1.89 MPa m¹/². The values for both laser treated surfaces fluctuated due to the variation in the surface hardness and the differing crack geometries. The surface finish of the ceramics prior to the laser treatment should also be considered where the unpolished (as-received) surface is more prone to cracking during the diamond indentation due to pre-existing manufacturing surface flaws and micro-cracks which was the case in the study.

4.2. Comparison of CO₂ laser surface treatment and fibre laser surface treatment of the Si₃N₄ engineering ceramic

4.2.1. Change in the surface hardness

The average hardness of the CO₂ laser radiated surface of the Si₃N₄ was 1028 HV which was - a reduction of 13% from the fibre laser radiated surface (1154 HV). This reduction in the surface hardness indicated that a softer surface layer was also produced by the CO₂ laser radiation in comparison to that of the fibre laser radiation. The hardness values ranged between 264 and 1449 HV for the CO₂ laser radiated Si₃N₄ and between 788 HV to 1449 HV for the fibre laser radiated Si₃N₄ as shown in Figure 8. It is evident from Figure 8 that the fluctuation in the hardness value was large. The reason for this was due to the surface containing an oxide layer of around 100 to 150µm thickness resulting from both laser treatments which was somewhat softer and more uneven in comparison to the laser unaffected surface. As such, the diamond indenter
penetrated deeper into the surface in some of the regions than in others, which is why the diamond indentation in Figure 9 and Figure 10 are not symmetrical.

Figure 9 and Figure 10 presents an example of a diamond indentation produced and the accompanying crack geometry. It can be seen from the two images that the diamond indentation produced on the CO₂ laser radiated Si₃N₄ (see Figure 9) is larger than that of the fibre laser radiated surface (see Figure 10). Both the CO₂ and the fibre laser treated surface of the Si₃N₄ genuinely showed evidence of surface oxidation. The new surface was formed from the result of the Si₃N₄ ceramic being exposed to the atmosphere at high temperatures. This would have led to the possible compositional change where the Si₃N₄ was changed to SiO₂. Moreover, the occurrence of the white phase as illustrated in Figure 9 and 10 would also lead to some modification in the micro-structure of the Si₃N₄ ceramic as the white oxide layer would be formed above the normal surface of the Si₃N₄ which in turn would generate in-filling of the surface cracks in various areas and also cover the grains that would normally appear on the top surface layer. The change in composition of the Si₃N₄ was also confirmed from a previous investigation by Lysenko et al. [40]. A reduction in the crack length obtained on the CO₂ laser radiated surface occurred due to the oxide layer being somewhat thicker in various areas in comparison which showed lower surface hardness and the resulting crack lengths.

4.2.2. Change in the crack length

The crack lengths obtained from both of the laser radiated surfaces are presented in Figure 11. The average crack length obtained from the CO₂ laser radiation was 210μm and ranged between 135 to 295μm. This in comparison to the cracks produced by the Vickers indentation test of the fibre laser radiated Si₃N₄ was 16% lower. An average
crack length found was 242μm with a highest of 337μm and the lowest of 164μm for the fibre laser radiated surfaces. The fluctuation from the values in Figure 11 has resulted from the newly formed, uneven oxide layer after both of the laser surface treatments.

4.2.3. Change in the $K_{1C}$

The average $K_{1C}$ of the CO$_2$ laser treated surface was found to be 4.78 MPa m$^{1/2}$ and ranged between 2.74 MPa m$^{1/2}$ and 11.90 MPa m$^{1/2}$. This was 26% higher in comparison to that of the fibre laser radiated surface of the Si$_3$N$_4$ ceramic. The average $K_{1C}$ value for the Si$_3$N$_4$ after the fibre laser treatment was 3.51 MPa m$^{1/2}$. The highest $K_{1C}$ value obtained above the mean was 6.03 MPa m$^{1/2}$. The results are shown in Figure 12. The values also fluctuate considerably due to the variations found in the hardness and the crack lengths that led to generating an uneven surface profile as mentioned earlier in this study.

4.3. Differences between the CO$_2$ and the fibre laser surface treatment and the effects on the hardness, crack lengths and the $K_{1C}$ of the engineering ceramics.

4.3.1. Rationale for the change in the hardness

The results showed that a change in the hardness occurred from both of the laser treatments to the ZrO$_2$ and the Si$_3$N$_4$ engineering ceramics. However, the hardness produced by the CO$_2$ laser in comparison to the fibre laser was somewhat lower. This was due to the difference in the absorption of the mid infra-red wavelength CO$_2$ and the near infra-red wavelength of the fibre laser wavelength. Both the CO$_2$ and the fibre
laser wavelength, however, penetrate to a significant depth within the ceramics. Although, the CO₂ laser has the tendency to produce high interaction zones at the surface where as the fibre laser is penetrated deeper into the ceramic layer for the Si₃N₄ ceramic in particular. This produces more compositional change at the top surface radiated by the CO₂ laser as the white SiO₂ layer is produced which is somewhat softer in comparison to the parent surface. For the ZrO₂ ceramic, the fibre laser wavelength is somewhat transparent hence, the interaction is lower in comparison to the CO₂ laser interaction with the ZrO₂. This in turn will produce high local temperature and larger melt pool at the surface but yet it is still shallow in comparison to the fibre laser radiated surface. The larger melt zone intrinsically produces a bigger diamond indentation footprint in comparison to the fibre laser radiated surface and therefore has slightly lower hardness in comparison. This finding relate to the work of White et al. [41] who reported that an increase in the hardness of boron carbide ceramic by processing with the near infra-red wavelength of a Nd:YAG laser was found which comply with the higher hardness found with the near infra-red wavelength of the fibre laser.

Furthermore, taking into consideration of the effects produced by laser float zone (LFZ) melting and (LZM) of eutectic ceramics by several workers [41-49], it can be said that considerable change in the microstructure would occur after the laser material interaction has taken place with both the CO₂ and the fibre laser radiated ceramics in this work. Those changes are within the surface morphology, growth of oxide crystals, and changes in the grain size and direction would occur, formation of amorphous layers as well as decrease in porosity would occur which in turn would considerably affect the local characteristics and properties of the ceramics particularly in the case of the
surface hardness and the $K_{1c}$ which heavily influences the microstructure of the ceramics. Further investigation are being undertaken to justify the micro-structural modifications induced by the laser surface treatment.

### 4.3.2. Rationale for the change in the crack lengths and the end $K_{1c}$ of the ceramics

The increase in the hardness usually manifests as an increase in the crack length due to the ceramic becoming more brittle; however, this did not occur with surfaces of both CO$_2$ and the fibre laser radiation. A likely cause for this would the effect of crack healing as the pre-existing surface micro-cracks on the ceramic were filled and covered particularly by the fibre laser radiation. Also, the event of phase transformation would have occurred for both ceramics which led to a change in the $K_{1c}$ values.

Consideration must also be given to the event of strain hardening taking place as result of the fibre laser-ceramic surface interaction. The effect of strain hardening through movement of dislocations at elevated temperatures inherently could induce compression into the surface and sub-surface of the ceramic and through the effect of transformation hardening. If one considers the heat generated from irradiation by the fibre laser beam is likely to have caused the Si$_3$N$_4$ in particular to transform from the $\alpha$ to $\beta$ state at 1600 °C, as stated by Jiang et al. [50]. This intrinsically would have caused the observed increase in the hardness of the Si$_3$N$_4$ to 3600 HV in particular. Since, the temperature during the fibre laser processing has been found to be much higher than 1600°C [50] for both ceramics, phase transformation of $\alpha$ - $\beta$ phase will inherently
occur within the Si$_3$N$_4$ and from monoclinic (M) phase to active tetragonal (T) phase would occur within ZrO$_2$ during the fibre laser irradiation.

An investigation by Moon et al. [51] found that the fracture toughness of Al$_2$O$_3$ and Si$_3$N$_4$ ceramics was improved considerably by generating dislocations within the ceramics by plastic deformation (shot blasting) and then annealing to temperatures of 1500°C. Work by Shukla and Lawrence [21] showed that the fibre laser surface processing of the Si$_3$N$_4$ and the ZrO$_2$ occurred above 2000°C and could have led to an increase in the hardness as the movement of dislocations at high temperatures would have induced a degree of residual stress into the ceramic in the form of compression.

In account of the fibre laser induced compression (see Figure 13), the tension would have needed to overcome the compression in order to propagate a crack. Therefore, the cracking of the ceramics was much smaller with the fibre laser radiated surface in comparison to that of the CO$_2$ laser radiation. This meant that the tension induced by the 49.05 N load to produce a crack on the fibre laser treated surface was much smaller than the induced compression. This rational goes some way to explaining the reason why smaller crack lengths have been found on the fibre laser treated ceramic (particularly with Si$_3$N$_4$) surfaces in comparison with the CO$_2$ laser treated surface. Values obtained for the hardness, crack length and the $K_{IC}$ for the Si$_3$N$_4$ and the ZrO$_2$ ceramics treated by both the fibre laser and the CO$_2$ laser are presented in Table 1.
4.4. Other influential aspects affecting the $K_{1C}$ of the laser treated ceramics

4.4.1. Differences in laser parameters

The differences within the $K_{1C}$ results achieved by the CO$_2$ and the fibre laser surface treatment have occurred due to several aspects which should be considered. Those are the material absorption; laser beam delivery system; wavelength and the brightness (power per unit area). The beam quality of the CO$_2$ laser and the fibre laser are in the same region ($TEM_{00}$). Therefore, the effect of the beam quality factor is minimal.

However, it is important to consider the way in which the Gaussian beam of $TEM_{00}$ is delivered as this would have an influence on the interaction between the ceramics and the specific laser used. Since the CO$_2$ laser is delivered by a galvanometers and stationary mirrors the beam is focused at a fine spot size whereas the fibre laser beam is delivered by a fibre cable which is less focused. It is required that a larger beam size is used for ceramic surface treatment so that the laser beam is distributed evenly onto the ceramic. In this, case a fibre laser with a low focused beam in comparison to that of the CO$_2$ would be more ideal especially for the surface treatment of the ceramics.

The material absorption co-efficient is varied with different laser wavelengths. As some wavelength are better absorbed by the ceramics than others. The CO$_2$ laser wavelength absorption with ceramics is about 87% whereas the fibre laser wavelength absorption is about 92%. This means that the fibre laser wavelength is more absorbed into the material and exhibits better interaction zone. This produces more photon energy that is induced onto the ceramic surface. This in turn, produces high temperatures during the fibre laser processing which allows the ceramics to undergo phase and compositional changes and affect the hardness and the resulting crack
geometries in different ways and has also affected the end $K_{IC}$ result from the two different laser sources used.

The difference in the laser brightness (luminance) between the two lasers used would also have an effect during the ceramic interaction as the fibre laser is much brighter than the CO$_2$ laser which indicates that there is more power per unit area being executed at the ceramic surface. On account of this, it is indicative that the luminance at high power per unit area is larger with the fibre laser and produces more interaction, high processing temperatures and rather leads to transformation hardening of the ceramics which is not seen with the CO$_2$ laser surface radiation.

### 4.4.2. Influence of the ceramics surface condition

The CO$_2$ and the fibre laser both were executed on the as-received surfaces of the ZrO$_2$ and the Si$_3$N$_4$ ceramics which comprised of some degree of surface flaws such as porosity and micro cracks and machine induced scaring. Due to this, the possibility of crack propagation increases during the diamond indentation tests. If the surface flaws were minimized in this study by introducing grinding and polishing of the near surface layer of the ceramics then the crack propagation during the indentation test would have been somewhat low. This is also true because the ground and polished surfaces are free from the surface impurities and has the tendency to induce compressive stress and allow the ceramics to be more resistant to cracking [39]. This in turn, also increases the surface $K_{IC}$ as the resulting crack lengths from the indentation tests are reduced which also indicate that the surface of the ceramics are less prone to cracking.
4.4.3. Effects of phase transformation and change in composition

A new surface was formed especially on the top surface of the Si$_3$N$_4$ ceramic after being radiated by both CO$_2$ and the fibre laser (see Figure 9 and Figure 10). This was because of the Si$_3$N$_4$ ceramic being exposed to the atmosphere at high temperatures and led to a possible change in the compositional as the Si$_3$N$_4$ was changed to SiO$_2$. Consequently, the effects with ZrO$_2$ were also identical after conducting both the CO$_2$ and the fibre laser surface treatments. A change in composition within the ZrO$_2$ would have also taken place where the top surface of the ZrO$_2$ was changed to ZrCO$_2$. A compositional change within the laser radiated ZrO$_2$ and Si$_3$N$_4$ was also previously confirmed with the work of Shukla and Lawrence [52]. A change in composition after the fibre laser surface treatment in turn, would affect the hardness of the ceramics which inherently influenced the crack geometry during the Vickers indentation test and furthermore, the end $K_{IC}$ values.

4.4.4. Effects of the Vickers indentation test and parameters used within the $K_{IC}$ equation

The Vickers indentation method is easy to set-up and cost effective but it still has several flaws such as the results obtained from the hardness test heavily depending on user’s ability to detect the crack lengths and its geometry. The $K_{IC}$ values could be much improved if the surface hardness values and the resulting crack geometries were consistently balanced with minimal fluctuation. The fluctuations found in the mean hardness from the results of this study were up to 11 %. This in comparison with the values for the ceramics given in the literature were 1 % higher from the ± 10 % range (error) given in [2]. Error of at least 1 % (minimum) between the hardness values found in this study and the literature can be an exempt from being a non-conformance and may be considered to pass through the quality requirements if the hardness test was used for a (real life) ZrO$_2$ ceramic engineering component/product. This could be found from adopting other indentation methods and by using many of the other existing empirical equations.
Calculation of fracture toughness is somewhat difficult due to various uncertainties such as the selection of the most appropriate equation; input parameters which compliment the equation used; the surface conditions of the ceramics and the ceramics response to the diamond indentations. Consideration should be given to two parameters that can influence the $K_{1C}$ of the ceramics here in this investigation and on a general note. Those parameters are; the indentation load and the Young’s modulus. Whereas the indentation load was kept constant in this study, so the effects of this parameter were zero. However, the Young’s modulus would also influence the $K_{1C}$ of the Si$_3$N$_4$ since an increase in the ratio of stress and strain which in turn increases the Young’s modulus value and affects the end $K_{1C}$ value. If the effect of Young’s modulus was ignored then the $K_{1C}$ value for the CO$_2$ laser treated surfaces would be reduced to 6% on average.
Fracture toughness property ($K_{1C}$) of the ZrO$_2$ and Si$_3$N$_4$ engineering ceramics was conducted following a CO$_2$ and a fibre laser surface treatment. Vickers indentation technique was employed for determination of $K_{1C}$. The following conclusions were found from comparing the two laser sources applied to the ZrO$_2$ and the Si$_3$N$_4$ ceramics:

- The CO$_2$ laser radiated surfaces in comparison to the that of the fibre laser radiated surface modified the $K_{1C}$ of both ceramics was found by the CO$_2$ and the fibre laser surface treatment in comparison to the as-received surfaces.

- The $K_{1C}$ values found on the CO$_2$ laser radiated surface of the Si$_3$N$_4$ was 3% higher in comparison to that of the fibre laser. This was due to the near surface of the Si$_3$N$_4$ being soft and was lower in hardness which further increased the fracture resistance.

- The effects were different with the ZrO$_2$ ceramic to that of the Si$_3$N$_4$ as the fibre laser surface treatment on this occasion had produced a rise of 34% compared to that of the CO$_2$ laser radiation. This was because of low crack propagation which resulted from the Vickers indentation test and inherently affected the end $K_{1C}$ of the fibre laser radiated surface of the ZrO$_2$ engineering ceramic.

- The $K_{1C}$ modification of the two ceramics treated by the CO$_2$ and the fibre laser was also believed to be influenced by the different laser wavelengths and its absorption co-efficient of the ceramics as well as the beam delivery system and the brightness of the two laser types applied.
The change in wavelength affects the absorption of the laser energy. The fibre laser was induced deeper into the surface of the ceramics in particular the Si$_3$N$_4$ whilst the CO$_2$ laser produced larger profile and more broader laser affected region which in turn generated a larger oxide layer which was somewhat softer in comparison to the fibre laser radiated surface.

For the ZrO$_2$ ceramic, the fibre laser wavelength was somewhat transparent so the laser-material interaction was lower in comparison to the CO$_2$ laser interaction with the ZrO$_2$. High local temperature and larger melt pool at the surface were therefore produced. Furthermore, the larger melt zone produced a bigger diamond indentation foot-print in comparison to the fibre laser radiated surface and comprised of slightly lower hardness in comparison.
